ACKNOWLEDGMENTS AND DEDICATIONS

The idea for this encyclopedia came from conversations with scientists and managers who wanted to see a treatise on ecosystems and biomes. We then embarked on the *Encyclopedia of the World's Biomes* not to redefine and reclassify biomes but to highlight groups of similar ecosystems using existing biome classifications and how humans have shaped and interacted with these ecosystems.

Although this work is approximately 300 articles, we knew at the outset we could not cover all the amazing places on Earth. It is simply too broad, so we tried to provide some of the highlights for you and encourage you to keep looking for more.

The *Encyclopedia of the World's Biomes* is dedicated to the courage of Greta Thunberg.

EDITOR BIOGRAPHIES

EDITORS-IN-CHIEF

Michael I. Goldstein has worked on many applied management issues across terrestrial and aquatic systems, addressing pesticides, dispersed recreation, development, timber harvest, and other forms of resource extraction. Mike served as the Ecology and Conservation Editor of Elsevier's major reference work *Earth Systems and Environmental Sciences* from 2012-2020 and is Co-Editor-in-Chief of the *Encyclopedia of the Anthropocene*, this *Encyclopedia of the World's Biomes*, and the forthcoming *Imperiled: The Encyclopedia of Conservation*. Mike is a planner and biologist for the US Forest Service in Juneau, Alaska. In his spare time, Mike coaches skiing, enjoys fishing and camping in remote places, and teaching his three children the joys of life.

Dominick A. DellaSala is President and Chief Scientist of the Geos Institute in Ashland, Oregon, and former President of the Society for Conservation Biology, North America. He is an internationally renowned author of over 200 publications on forest ecology, endangered species, conservation biology, and climate change. Dominick has given keynote talks ranging from academic conferences to the United Nations Earth Summit. He has been featured in hundreds of news stories and documentaries, testified in the US congress numerous times, and received conservation leadership and book writing awards. He is on the editorial board of Elsevier's *Earth Systems and Environmental Sciences* as Global Change Editor, co-editor of the *Encyclopedia of the Anthropocene* (Elsevier), and subject editor of several scientific journals. Dominick is motivated by his work to leave a living planet for his daughter (who has Lyme disease) and all those that follow.

Section Editors

Mark J. Costello is an ecologist with a long-time interest in biodiversity and biogeography from local to global scales, particularly in marine and freshwater ecosystems, and applications in conservation and aquaculture. He is a professor at Nord University (Norway) and the University of Auckland (New Zealand). Born in Ireland, he studied in Galway and Cork, followed by postdocs at the Marine Biological Association in Plymouth England, and the Scottish Office and Napier University in Scotland. He became a lecturer in Trinity College University of Dublin, Managing Director of EcoServe (an environmental consulting company in Ireland), and Executive Director of the Huntsman Marine Science Centre, Canada. He has supervised over 50 MSc and PhD students and published over 200 peer-reviewed papers. Driven by a life-time fascination with nature, he is especially pleased to have pioneered a new field of “ocean biodiversity informatics” and, in that, played leadership roles in the development of useful world databases that list and map biodiversity across land and sea.

Dominic DiPaolo is the owner of Native Ecosystems, an ecological consulting company specializing in special status plant, bryophyte, and lichen surveys; native plant propagation; ecological landscape planning; and GIS mapping. Until recently, he worked with the National Park Service’s Inventory and Monitoring Program and Southern Oregon University, completing vegetation classifications and maps of Crater Lake National Park, Lava Beds National Monument, and Oregon Caves National Monument and Preserve. He currently resides in Ashland, Oregon, United States.

Scott Elias received both an undergraduate degree and a PhD in Environmental Biology at the University of Colorado, Boulder. Following postdoctoral fellowships in Canada and Switzerland he returned to the Institute of Arctic and Alpine Research at the University of Colorado, where he pursued research in Quaternary paleoenvironments from 1982 to 2000. In 2000 he took a lectureship in Quaternary Science in the Geography Department of Royal Holloway, University of London, where he became Professor of Quaternary Science in 2007. He has served as editor-in-chief of the first and second editions of the Encyclopedia of Quaternary Science, published by Elsevier. In 2012 he became editor-in-chief of the online Reference Module in Earth Systems and Environmental Sciences. Scott’s research has focused mainly on the reconstruction of Late Pleistocene environments from the Alaska, the Rocky Mountains, and the American Southwest. He retired from Royal Holloway in 2017 and returned to Colorado, where he continues his research in paleoenvironments and his editorial duties.

John E. Quinn holds a PhD in Applied Ecology from the University of Nebraska-Lincoln. He currently is an associate professor of Biology at Furman University. His research and teaching emphasize concerns related to biodiversity conservation and sustainability; in particular, avian ecology, conservation in managed ecosystems at local and global extents, and sustainability for landscape planning. Currently his research focus is on how agricultural and urban landscapes and soundscapes in Upstate South Carolina can be managed to conserve biodiversity and enhance ecosystem services and the governance tools to reach community goals.

Courtney E. Quinn holds a PhD in Leadership Studies from the University of Nebraska-Lincoln. Her specific teaching and research interests revolve around sustainability and environmental leadership. Courtney has taught classes in Sustainability Science at Furman University since 2014 where she also serves as the Faculty Leadership Development Coordinator. She has published in the areas of sustainability science, human dimensions of natural resources, and higher education pedagogy, specifically in regard to the development of critical thinking in college students.

Lowell Suring joined Northern Ecologic L.L.C. in 2009 after serving as a Wildlife Ecologist with the USDA Forest Service at several locations in Minnesota, Alaska, and Idaho since 1980. He also held permanent positions with the US Fish and Wildlife Service in New Mexico and with the New York State Department of Environmental Conservation. Lowell is a Certified Wildlife Biologist and an elected Fellow of The Wildlife Society. He is active in The Wildlife Society at State Chapter, Section, and International levels. His professional interests include the development and implementation of analytical techniques and tools that may be used to evaluate the capability of habitats to support wildlife and the effects of land management activities on habitat capability.

Abstract

Despite the widespread use of the term biome, systematic, multi-scaled biome classifications are hard to come by. This may be in part because biomes represent large-scale ecosystems, and the complexity of ecological and biotic factors makes it hard to classify them at these large scales. In addition, humans play a large role in shaping biomes, such that both natural and anthropogenic biomes need to be treated. Here we introduce the International Vegetation Classification (IVC), based on the EcoVeg approach, as a useful, multi-scaled and comprehensive terrestrial classification that can inform biome concepts. We rely on vegetation as a primary criterion (typical of many approaches to biome concepts) while noting that ecoregional and functional approaches add additional valuable perspectives. The IVC uses an 8-level hierarchy for both natural and cultural vegetation. For natural vegetation, the IVC includes three upper (formation) levels, three mid (physiognomic-biogeographic-floristic) levels and two lower (floristic) levels. The IVC is most advanced in North and South America, but we describe a number of other major vegetation classifications with similar approaches that allow for a collaborative approach to describing ecosystems across the globe at all scales. The IVC provides a consistent thematic framework to support broad-scale vegetation mapping, inventory and assessment, including applications to both the IUCN Red List of Ecosystems and NatureServe Conservation Status Assessment protocols. The classification approach meets the need for a dynamic, 8-level catalogue of types for all existing vegetation, including large-scale ecosystems or biomes. The open, peer-review model allows for ongoing improvement by ecologists, while always providing comprehensive versions for users.

Biomes, Ecosystems and Vegetation

After several decades of contributions, in 2005 the 26th volume of the *Ecosystems of the World* series was completed (<https://www.elsevier.com/books/book-series/ecosystems-of-the-world>). Remarkable in its scope, the purpose of the series was “to describe the structure and functioning of all major types of ecosystems, whether aquatic or terrestrial, natural or subject to human influence—in some cases virtually man-made (like greenhouses, fishponds, or intensive animal production).” Most important for our purposes here, the subjects covered by *Ecosystems of The World* are divided by “ecosystem types or biomes.” Which raises the question as to the parallels between those volumes and the types covered in the *Encyclopedia of World Biomes*. To do so requires some decisions as to whether ecosystems and biomes are the same thing and how they are classified. Here we introduce the International Vegetation Classification (IVC) as one tool for understanding the range of variability of large biome-scale terrestrial ecosystems on land and aquatic margins. But to do that we first need to explore the relationship of ecosystem to biome.

Although many authors have offered definitions of an ecosystem, Keith et al. (2013) note that most encapsulate four essential elements implicit in Tansley's (1935) original concept: (i) a biotic complex or assemblage of species; (ii) an associated abiotic environment or complex; (iii) the interactions within and between those complexes; and (iv) a physical space in which these operate. Thus, ecosystems are defined by a degree of uniqueness in composition, structure and processes (involving the biota and the environment) and a spatial boundary. We follow Keith et al. (2013) in noting that terms such as “ecological communities,” “ecological systems,” “natural communities,” “habitats,” “biotopes,” and “vegetation types” are often applied as operational synonyms of “ecosystem types” for the purposes of classifying ecosystems.

For Tansley (1935), the biome was essentially an expression of a large-scale ecosystem: “The fundamental concept appropriate to the biome considered together with all the effective inorganic factors of its environment is the ecosystem” (Tansley, 1935). And, for terrestrial biomes “vegetation is of primary importance,” a criterion that is still currently maintained for almost all biome classifications (Moncrieff et al., 2016; Mucina, 2018). This in part stems from its role in primary production and as an “engineer” in many terrestrial and shallow aquatic ecosystems, but also from descriptive convenience—the structural and compositional features of vegetation are readily observed, and therefore useful descriptive tools. Thus, for our purposes, biomes are large-scale ecosystems, and vegetation has historically been the most productive way to describe and classify them. That said, animals, soils and other ecosystem components need to be addressed to fully understand the key processes and interactions of the biome.

Because ecosystems range across multiple spatial and temporal scales, a classification of ecosystems will be most valuable when they can operate across those scales (i.e., a biome-scale classification of ecosystems is not enough). Given the complexity of dealing with ecosystems, and a multitude of purposes, it's not surprising that ecologists have devised various classification systems. Three common ones are ecological site classifications, ecoregional classifications, and vegetation classifications (Fig. 1). They can be used separately or together to classify ecosystems, depending on the need. For example, WWF ecoregions (Dinerstein et al., 2017) can be

Fig. 1 Some commonly used, and complementary, approaches to classifying ecosystems, including large-scale ecosystems or biomes. Each approach can be used on its own or in collaboration with others to define ecosystems, including large-scale ecosystem or biomes.

used as a regional, spatially explicit, biome-scale classification, or it can be used in conjunction with the IVC to describe variation in ecosystem types found within and across ecoregions (Dixon et al., 2014).

To meet the need of characterizing the earth's terrestrial ecosystems, and to address critical conservation and resource management needs, biome-scale classifications should encompass both natural and cultural ecosystems. Indeed, the scope of the ecosystem concept can be applied to interweave these two together, without subsuming one into the other, to include both human and natural processes and disturbances within what are termed "social-ecological systems;" namely, linked systems of people and nature (Berkes and Folke, 1998). Finally, ecosystem classifications will also need to consider all three realms of ecosystems (terrestrial, freshwater, and marine), a task underway by an IUCN working group (Keith et al., 2019). Here we restrict ourselves to terrestrial biomes.

Why Include an IVC Perspective on Biomes?

In much of the literature, there is a considerable overlap and confusion between the concepts of biome, bioregion, ecosystem, and ecoregion among others, likely due to the plurality of meanings included in the word biome. The confusion is notable due to the mixture of definition, criteria, and hierarchical levels between concepts and terminology that place different emphasis on different definitional features, such as ecoregions, ecosystems, ecological systems, ecological divisions, biomes, ecozones, formations, bioregions, etc. A classification for biomes should lead us toward a parsimonious methodological and nomenclatural standardization able to explain and predict causally the distribution and global characteristics of the biomes based on a set of criteria or quantifiable variables. The classification should describe the diversity and dynamics of terrestrial ecosystems, span the full range of spatial and geographic scales across the globe, and provide knowledge of reference conditions and current states of ecosystems required to make decisions about conservation and resource management. There are imperatives to predict terrestrial ecosystem responses to alternative scenarios of environmental change and to develop an evidence base for adaptive management that seeks to reduce risks of ecosystem degradation and collapse. Assessing these risks, diagnosing their causes and designing management solutions to abate them depends critically on a basic understanding of the ecological processes and mechanisms that drive ecosystem change (Keith et al., 2013).

Despite these needs, there are few options for a comprehensive, operational, multi-scaled ecosystem classification, one that can scale down from large-scale biome patterns to finer-scale vegetation (plant community) patterns, or vice-versa. The IVC is currently unique in providing both global and continental biome-scaled ecosystem types that can be further resolved into regional to local ecosystem types (Faber-Langendoen et al., 2018). Collaboration with colleagues is needed to fully extend its application across the globe, in conjunction with other global, regional and national efforts. Still, although vegetation provides the primary basis for the IVC approach to classifying biomes, it is only part of what is needed to fully describe the key processes and interactions that govern biomes. Thus, the IVC and other such classifications are best seen as facilitators of the larger goal of understanding how ecosystems work.

Scaling ecosystems across the globe will always have limitations, given the wide diversity of species, growth forms, regions and ecological factors. We can look for some rough correlation between levels of ecological organization and spatial and temporal scales, but there are no universal rules. The IVC seeks to do this largely from a structural-compositional based perspective, interpreted and segmented along ecological gradients. More work is needed to develop models that integrate the IVC patterns with ecological processes, though recent mapping efforts in the Americas and Africa holds promise (Sayre et al., 2013; Ferrer-Paris et al., 2018).

Before describing the IVC in detail, we note that discrete classification of biomes is not always a goal, particularly when continuous attributes (such as NDVI) of an ecosystem or biome can describe certain functions or processes (Higgins et al., 2016).

Overview of the International Vegetation Classification

IVC and the EcoVeg Approach

The primary purpose of the IVC is to provide a consistent, systematic, and authoritative description and classification of terrestrial ecosystems, based primarily on vegetation patterns and their relationships with ecological, biogeographic, dynamic, and human processes. The IVC is based on the EcoVeg approach, as summarized in Faber-Langendoen et al. (2014, 2016, 2018). Briefly, the IVC was developed by NatureServe, in collaboration with partners of the US National Vegetation Classification (USNVC), including US federal agencies and the Ecological Society of America (FGDC, 2008), Canadian NVC (Baldwin and Meades, 2008) and others. The IVC is used widely by states, provinces and countries in the Americas that are part of the NatureServe Network. Initially, the IVC and USNVC partners adopted a strongly physiognomic approach for the upper levels, with floristic units nested below; in 2008, they supported the development and implementation of the EcoVeg approach for the USNVC (FGDC, 2008). The approach builds on the traditional physiognomic-floristic-ecological classifications that have been developed over many years (Faber-Langendoen et al., 2014). These perspectives also share a central philosophy with floristic-ecological approaches, such as the Braun-Blanquet approach (Westhoff and van der Maarel, 1973), and the biogeoclimatic approach (MacKenzie and Meidinger, 2018); namely, that vegetation types should be constructed in the context of ecological, dynamic, and biogeographic considerations. The EcoVeg approach integrates these considerations for all vegetation types at multiple thematic scales.

Guiding Principles

The IVC used the guiding principles from the EcoVeg approach, briefly summarized here (see Faber-Langendoen et al., 2014 for more details):

1. The classification is based on *existing vegetation* types, defined as the plant cover—including floristic composition and abundance and vegetation structure—documented at a specific location and time, under specified ecological conditions, and preferably described at an optimal time(s) during the growing season. Thus, as applied to biomes, we do not address potential natural vegetation, though the IVC does address historic patterns of vegetation that existed at time periods in the past.
2. Vegetation types are characterized by *full floristic* and *growth form (physiognomic)* composition, which together express *ecological* and *biogeographical* relations.
3. Vegetation characteristics can be described as a function of both *natural* and *cultural (or anthropogenic)* processes.
4. Characterizing and describing vegetation types is best accomplished using *plot data*, including both floristic and environmental site data, which are collected and compiled using *systematic protocols and survey techniques*.
5. Vegetation types can be defined using a *number of differentiating criteria*, depending on the level, including diagnostic, constant and dominant species, dominant and diagnostic growth forms, and compositional similarity (Table 1). The most useful criteria are those that express *environmental* and *biogeographical relationships* that clearly distinguish types. These criteria should be defined for application in the field or lab, so that *recognizable and unambiguous field characteristics* are provided to ensure consistent identification using keys and other tools. Types are defined both extensively (e.g., a full list of types is developed within each level of the hierarchy, a list of plots is attributed to each type, range maps are provided, etc.) and intensively (e.g., concise differentiating criteria are provided for each type, including diagnostic and dominant species, growth forms, environmental site factors and biogeography).
6. Classification and field recognition of vegetation types creates a conceptual framework of vegetation pattern and process that provides a foundation for multiple applications, e.g., *vegetation mapping, monitoring, modeling*.
7. Differentiating criteria for vegetation types can be arranged *hierarchically*, from *upper levels* primarily based on general growth forms, to *middle levels* based on specific growth forms and floristics that includes suites of general and regional combinations of characteristic species, to *lower levels* based primarily on gradients in floristics and ecology. At all levels, existing vegetation provides the primary criteria for definitions and descriptions within the hierarchy, but the hierarchical organization may be based on the existing ecological and biogeographical relations expressed by the vegetation.

Table 1 Brief summary of criteria for natural and cultural vegetation (for fuller description and references, see Faber-Langendoen et al. (2014)).

Criteria	Natural Vegetation	Cultural Vegetation
Growth forms	Growth form criteria include (1) diagnostic combinations of growth forms, (2) dominant growth forms, singly or in combination; and (3) vertical and horizontal structure of growth forms. Growth forms are based on structural types (e.g., tree), leaf form (e.g., broad-leaved macrophyll), relative plant and leaf size, and seasonal activity pattern (e.g., summergreen)	Growth form criteria include (1) diagnostic patterns of growth forms, (2) dominant growth forms, singly or in combination, and (3) vertical and horizontal structure of growth forms.
Floristics	Floristic composition is summarized by the “ <i>characteristic species combinations</i> ” (or diagnostic combination of species), including (a) diagnostic species (character and differential species), (b) constant species, (c) dominant species; all linked to growth forms and structure above	Floristic (crop or managed species) criteria include: (1) diagnostic combinations of species/crop or managed types, (2) dominant species, reflecting similar agricultural or developed vegetation patterns, (3) vertical and horizontal structure of species. Together these criteria are evaluated in a human management context
Compositional similarity	Compositional similarity is defined as a measure of the similarity in the presence and/or abundance of plant species between two or more plots or types. At middle scales of vegetation pattern, where plots increasingly lack overlap in species composition, but occupy similar ecological and biogeographical space, compositional similarity is assessed using suites of diagnostic species and growth forms related to biogeographic patterns. Large scale compositional similarity is captured in the distinct pool of species found in different biogeographic regions	Not applicable
Ecological context	Criteria for ecological context include (1) biogeography (from large-scale biogeographic regions to regional biogeographic and biogeoclimatic zones), (2) climate (macro, <i>meso</i> , and microclimates), (3) disturbances (natural and cultural disturbances, and successional patterns), and (4) topo-edaphic factors, including the topographic features of elevation, slope and aspect, as well as edaphic factors, such as pH, moisture, nutrients, and texture	Criteria for ecological context include (1) climate (macro, meso, and microclimate), though human management activities often compensate for many of the climatic effects, (2) effects of human activities (e.g., plowing, mowing), and (3) topo-edaphic factors, including creation of ponds, plowing, modifications of pH, moisture, nutrients, and texture. Because many crop species are planted and maintained outside their provenance, biogeography is rarely considered in the description of cultural types

8. An integrated hierarchy of vegetation types is best established by considering *each level as both independent and inter-connected* in a *nested* relationship; i.e., criteria selected to differentiate levels in the hierarchy are sufficient to define and distinguish types of a particular level, thereby preventing it from being arbitrarily defined by the level immediately above or below in the hierarchy. Thus, for the development of vegetation types, the EcoVeg approach is both “top-down” and “bottom-up.”

Classification protocols for the IVC are fully described in Faber-Langendoen et al. (2018).

Natural and Cultural Vegetation

The IVC describes and classifies both natural and cultural vegetation. Thus, it can be used to describe large-scale anthropogenic biomes, such as cropland, hay meadows and pasture, and plantations (Ellis and Ramankutty, 2008), as well as natural biomes, such as native forests, grasslands, deserts and wetlands. *Cultural vegetation* possesses a distinctive structure and composition that is determined by the response to human intervention, such as (1) regularly spaced herbaceous vegetation with substantial cover of bare soil for significant periods of the year (usually determined by tillage, chemical treatment, or agricultural flooding), (2) vegetation consisting of highly-manipulated growth forms or structures rarely found under natural plant development (usually determined by mechanical pruning, frequent mowing, clipping, etc.), and (3) vegetation composed of species not native to the area that have been intentionally introduced to the site by humans and that would not persist without active management by humans (e.g., lawns, golf courses, plantations, arboreta). The drivers of cultural vegetation are largely human, and thus intertwined with cultural, historical and socioeconomic aspects that make it difficult to generalize patterns.

By contrast, *Natural and semi-natural vegetation* is composed predominantly of spontaneously growing sets of plant species with composition shaped by both abiotic (site) and biotic processes; these are vegetation types whose species composition is primarily determined by non-human ecological processes (Westhoff and van der Maarel, 1973). Within natural and semi-natural vegetation there is a spectrum of human activities (e.g., logging, livestock grazing, fire, introduced pathogens), but “ruderal vegetation” represents the most human-influenced natural vegetation. We define ruderal vegetation as “vegetation found on human-disturbed sites that may not have apparent recent historical natural analogs, and whose current composition and structure is not a function of continuous cultivation by humans and includes a broadly distinctive characteristic species combination, whether tree, shrub or herb dominated. The vegetation is often composed of invasive species, whether exotic or native, that typically have expanded in extent and abundance due to the human disturbances” (from Faber-Langendoen et al. 2014). The term “novel ecosystem” has been applied to this kind of vegetation. For example, forests found on abandoned farm fields in the northeastern United States contain both invasive exotic trees (e.g., *Acer platanoides*, *Robinia pseudoacacia*) and generalist native trees (e.g., *Acer rubrum*), as well as invasive shrubs and herbs (e.g., *Rhamnus cathartica*, *Alliaria petiolata*). Both the vegetation and ecological processes associated with these forests are distinct from more natural forests. Inclusion of both native and weedy vegetation within “natural vegetation” is perhaps akin to many botanical manuals that treat both native and naturalized species within their scope; yet these manuals exclude the multitude of cultivated species found in lawns, gardens, farm fields and plantations.

Classification of natural and semi-natural vegetation

Growth forms and floristic characteristics that reflect ecological and biogeographical variables are the primary properties of natural vegetation, and the dominant and diagnostic combinations of these properties are used to define all units of the hierarchy (Faber-Langendoen et al., 2014) (Table 1).

The growth form types provided in Faber-Langendoen et al. (2014, 2016), are used to characterize IVC types at broader scales. Six general growth form types (tree, shrub, herb, nonvascular, epiphyte, liana) are further subdivided into 29 specific growth form types (e.g., broad-leaved evergreen tree, succulent shrub, sclerophyllous shrub, and lichen) that are diagnostic for large-scale biomes, such as tropical rainforest, desert, or cliffs. At lower levels, the characteristic species combination (or diagnostic species combination) is considered a strong indicator of bioclimatic, biogeographic, geo-edaphic, and successional conditions.

The classification hierarchy for natural ecosystems consists of eight levels that are aggregated into three groupings: upper levels (L1–L3), middle levels (L4–L6), and lower levels (L7–L8) (Table 2a). The criteria outlined in the previous section are used to develop descriptions of each unit in the hierarchy, following a standard template.

Classification of cultural vegetation

The criteria for classifying cultural vegetation include growth forms, floristics, and ecological setting (Table 2b). The criteria largely correspond to that of natural vegetation, except that compositional similarity is not used, given the typical mono- or mixed dominance of many cultural vegetation types.

As with natural vegetation, the hierarchy consists of eight levels that are aggregated into three sets, but growth forms and structure play a greater role for classifying cultural vegetation. The criteria outlined in the previous section are used to develop descriptions of each unit in the hierarchy, with the utility and relevance of the criteria varying by level.

Supporting Infrastructure and Peer Review

The classification is maintained through a coordinating body that oversees the recognition and integration of new and revised vegetation types through a peer-review process. The goal of the process is to maintain a standard set of recognized vegetation types

Table 2a Hierarchical classification for natural vegetation, with example.

that represents the current best understanding of the universe of terrestrial ecosystems, based on vegetation and ecological characteristics.

NatureServe maintains the IVC, working in collaboration with international partners, such as the International Union for Conservation of Nature (IUCN), and with national partners, especially the USNVC (FGDC, 2008), Canadian NVC (Baldwin and Meades, 2008), Bolivian NVC (based on Navarro, 2011), among others. A future goal is to establish a formal international review panel that would oversee collaboration around national and international classifications (see section below “The IVC as the Basis for a Collaborative Framework Among Various Continental-National Approaches”). Revisions are based on quantitative plot-based analyses, literature review, and expert panel review. NatureServe staff maintain the IVC content and share the data with 82 member programs (US states, Canadian provinces and territories, and several Latin American countries). Information on the IVC for the Americas is available on the web at <http://natureserve.org/explorer> [see also below “Current Status of the IVC”].

Biome-Scale Levels of the IVC

We here describe the vegetation type levels most relevant to characterizing biome-scale ecosystems. Definitions and concepts are from Faber-Langendoen et al. (2014, 2016).

Formations: Global Biomes/Ecosystems

The upper levels of the IVC are based on the *formation*, a prominent concept throughout the history of vegetation classification. The formation is physiognomic-structural in character with supplementary ecological information and defined by dominance of a given growth form in the uppermost stratum of the community, or by a combination of dominant growth forms (Whittaker, 1975). These formations have been widely used to define biomes; as Moncrieff et al. (2016) state “Biomes refer to globally convergent vegetation formations similar in structure and function, explicitly ignoring floristic differences.” In the IVC, the two most relevant formation levels that correspond to many global biome concepts are formation subclass and formation (Table 3):

- *Formation Subclass (L2)*: defined by combinations of general dominant and diagnostic growth forms that reflect global macroclimatic factors driven primarily by latitude and continental position, or that reflect overriding substrate or aquatic conditions. Some biome classifications (e.g., the Walter scheme summarized by Mucina, 2018) distinguish between those formations determined largely by macroclimatic drivers (the so-called zonal biomes) from those determined by macro-hydrological and lithological factors (the so-called azonal biomes). We include the interactions of these factors along with natural disturbance processes in shaping the formation (Bond et al., 2005).
- *Formation (L3)*: defined by combinations of dominant and diagnostic growth forms that reflect global macroclimatic conditions as modified by altitude, seasonality of precipitation (e.g., bioclimate types such as pluvial, pluviseasonal, xeric, desertic), substrates, and hydrologic conditions (cf. “formation-type” and “biome-type” of Whittaker, 1975). Here again, the vegetation patterns reflect the interactions of these factors.

A complete list of IVC subclasses and formations is provided in Table 4.

Table 3 Comparison of various natural biome (large-scale ecosystem) classification approaches.

Biome scale	International Vegetation Classification	IUCN 2019 (Keith et al., 2019)	Terrestrial Ecoregions of the World (Dinerstein et al., 2017)
Purpose	Catalogue of ecosystem diversity at multiple scales relevant to conservation and management.	Ecosystem risk assessment and management, and natural asset accounting	Biogeography and spatial conservation planning
Global biome I	Formation Subclass (L2) ● Tropical Grassland, Savanna & Shrubland	Biomes ● Savannas & grasslands	Biome/Major Habitat Type ● Tropical and subtropical grasslands, savannas, and shrublands
Global biome II (“formation-type” and “biome-type” of Whittaker (1975))	Formation (L3) Combinations of dominant and diagnostic growth forms that reflect global macroclimatic conditions as modified by altitude, seasonality of precipitation, substrates, and hydrologic conditions. ● Tropical Lowland Grassland, Savanna & Shrubland	Ecosystem functional groups ● Pyric tussock savannas	–
Continental Biome (“formation” and “biome” of Whittaker (1975); Subzonobiome/ Azonal Biome subdivisions of Mucina (2018))	Division (L4) Combinations of dominant and diagnostic growth forms and a broad set of diagnostic plant species that reflect biogeographical differences in composition and continental differences in mesoclimate, geology, substrates, hydrology, and disturbance regimes. ● Brazilian-Parana Lowland Grassland, Savanna & Shrubland	Biogeographic ecotypes (in development)	Biogeographic Realm ● Neotropical
Regional (biome of Mucina (2018))	Macrogroup (L5) Moderate sets of diagnostic plant species and diagnostic growth forms that reflect biogeographical differences in composition and sub-continental to regional differences in mesoclimate, geology, substrates, hydrology, and disturbance regimes. ● Cerrado Savanna	Ecosystem types (L5) (in development)	Ecoregion ● Cerrado

The similarities in scaling biomes is not meant to imply that the units are necessarily equivalent. Levels of the IVC and other systems are only shown in relation to biome-scale patterns. Biome scale terms are adapted from Mucina (2018). IVC information from Faber-Langendoen et al. (2014), IUCN 2019 from Keith et al. (2019), Terrestrial Ecoregions of the World from Dinerstein et al. (2017). Bulleted lines provide an example of a type developed within each level for each classification approach.

7.D. Agricultural & Developed Aquatic Vegetation	7.D.1. Agricultural Aquatic Vegetation* 7.D.2. Developed Aquatic Vegetation*

There are 13 natural and 4 cultural formation subclasses (Level 2; see also global biome I in Table 3) and 37 natural and 13 cultural formations (Level 3, see also global biome II in Table 3). * indicates a wetland formation.

Adapted from Faber-Langendoen D, Keeler-Wolf T, Meidinger D, et al. (2016) *Classification and description of world formation types*. Gen. Tech. Rep. RMRS-GTR-346. Fort Collins, CO: US Department of Agriculture, Forest Service, Rocky Mountain Research Station.

Divisions: Continental Biomes/Ecosystems

Moving from global biomes to continental biomes introduces the role of large-scale species pools, broadly distinct growth form types, and their biogeographic patterns, as defined by the Division level (Table 3).

- *Division (L4)* is defined as the combinations of dominant and diagnostic growth forms and a broad set of diagnostic plant species that reflect biogeographic differences in composition and continental differences in mesoclimate, geology, substrates,

hydrology, and disturbance regimes. Whereas the formation level (L3) is more strictly physiognomic, the division level includes both physiognomic and floristic criteria. The term “Division” was adopted from the Braun-Blanquet approach, which proposed it as a level above the “class” (Westhoff and van der Maarel, 1973).

In many respects, the division concept is also equivalent to the term “biome,” but as a continental or regional biogeographic concept. For example, the “Nama-Karoo” biome of South Africa is largely equivalent to a division.

With the introduction of the division concept and floristic criteria, the upper level formation (global biome) types can be subdivided by continental scale biogeographic species pools. Thus, the Tropical Lowland Humid Forest formation is divided into several South American divisions (Amazonian Lowland Humid Forest, Brazilian-Parana Lowland Humid Forest) and African-Madagascan divisions (Guineo-Congolian Evergreen & Semi-Evergreen Rainforest, and Malagasy Evergreen & Semi-Evergreen Rain Forest) (see also Tropical Dry Forest example in Fig. 2). Typically, suites of diagnostic (character) species are selected that are restricted to a division type, along with the dominant species that express the dominant growth forms. In turn, from the bottom-up, shared growth forms among division types, which reflect a set of shared climatic and edaphic factors, lead to their placement within the same formation (though the level of convergence should not be overstated, cf. Moncrieff et al., 2016).

Macrogroup: Regional Ecosystems

Continental biomes may be further subdivided by a suite of species, growth forms and structure that reflect regional climate, substrate, disturbance and biogeographic patterns. These factors play into the definition of the macrogroup level (Table 3).

Fig. 2 Division and macrogroup types for Tropical Dry Forest & Woodland formation (International Vegetation Classification) in the neotropics. The number after each letter is a database code for the IVC division (see Faber-Langendoen et al., 2018, Supplement S4). Faber-Langendoen D, Baldwin K, Keeler-Wolf T, et al. (2018) The EcoVeg Approach in North America: U.S., Canadian, and International Vegetation Classifications. *Phytocoenologia* 48: 215-237, www.borntraeger-cramer.de/journals/phyto; Comer PJ, Hak JC, Josse C and Smyth R (2020) Long-term loss in extent and current protection of terrestrial ecosystem diversity in the temperate and tropical America. *PLOS One* (in press).

- *Macrogroup (L5)* is defined by moderate sets of diagnostic plant species and diagnostic growth forms that reflect biogeographic differences in composition and sub-continental to regional differences in mesoclimate, geology, substrates, hydrology, and disturbance regimes.

A macrogroup type typically contains a moderately large set (dozens) of strongly diagnostic species that share a broadly similar physiognomy and ecology in response to continental, sub-continental, or regional differences in ecological factors (Table 3). Thus, the macrogroup expresses the floristic, growth form and regional ecological factors that separate vegetation types within a division. For example, in South America, the Amazonian Lowland Humid Forest division contains seven macrogroups based on species changes that reflect regional climate and elevational gradients: Central Amazon Humid Forest, Northern Amazon Humid Forest, Southern Amazon Humid Forest, Southwestern Amazon Lowland Humid Forest, Southwestern Amazon Subandean Humid Forest, Western Amazon Lowland Humid Forest, Western Amazon Subandean Humid Forest. Similarly, the Californian Scrub & Grassland Division is based on both a variety of distinct species and distinct growth form patterns, e.g., California Chaparral and the California Coastal Scrub. These macrogroup types are probably scaled at a level finer than most biome classifications, and they are perhaps better seen as the key level below biome that facilitates understanding the variation within a continental biome.

The macrogroup is similar to the “class” level of the Braun-Blanquet approach (Westhoff and van der Maarel, 1973), opening up the possibility of assembling the European vegetation types within continental biomes or divisions of the IVC (see section below “The IVC as the Basis for a Collaborative Framework Among Various Continental-National Approaches”).

Comparison of IVC Biome-Scale Levels With Other Global Classifications

In previous publications, we demonstrated that our formations have many parallels with other large-scale vegetation or biome concepts, both in concept and in number of types (Faber-Langendoen et al., 2014, Appendix D). Here we focus specifically on current classifications that are multi-scaled and biome-like in their approach, global in scope, and “operational” (having a user group that is actively developing, refining and applying type concepts through database descriptions and maps) (Table 3).

Each of the three major classifications in Table 3 are structured to meet different purposes. The Terrestrial Ecoregions of the World (Dinerstein et al., 2017) emphasizes biogeography and spatial conservation planning; the IUCN approach (Keith et al., 2019) is designed for ecosystem risk assessment and management, as well as natural capital accounting; it also provides a framework for synthesis across terrestrial, freshwater and marine realms; the IVC provides a catalogue of terrestrial ecosystem diversity focused on vegetation traits and ecological relationships at multiple scales relevant to conservation and resource management. All three bring in biome concepts adapted to their purpose. Thus, they offer complementary attributes; as an ensemble, they are a potentially powerful toolbox.

The IVC as the Basis for a Collaborative Framework Among Various Continental-National Approaches

The IVC is global in scope, with comprehensive descriptions for all natural and cultural formations (L2, L3) (Faber-Langendoen et al., 2016). At the division level, only natural grasslands have been completely assessed across the earth (Dixon et al., 2014), but all natural types are comprehensively developed down to macrogroup across the Americas (Table 5) and for Africa (Sayre et al., 2013).

Table 5 Current degree of completeness for natural vegetation types within the Americas.

Level	IVC North America (Canada, US)	IVC Latin America	IVC Americas	IVC global
Class	6	6	6	6
Subclass	11	13	13	13
Formation	27	29	34	36
Division	57	121	140	(est. 447) ^b
Macrogroup	156	292	375	(est. 1196) ^b
Group	410	~728 ^a	1059 ¹	TBD
Alliance	TBD	TBD	TBD	TBD
Association	TBD	TBD	TBD	TBD

Number of types for each level of the hierarchy are shown for the United States, Canada, and across the Americas, as of Sep. 1, 2016. The IVC-Americas includes all units currently reported by NatureServe for Canada, continental US (excluding Hawaii and the territories of American Samoa, Guam, and Mariana Islands), Caribbean (including Puerto Rico and Virgin Islands), Central America, and South America.

^aBased on 617 Ecological System types for South America (Josse et al., 2003). Ecological System types are typically equivalent to or somewhat finer than IVC groups.

^bIVC units for the Americas cover 31.1% of the globe, excluding Antarctica. Multiplying the Americas numbers by 3.19 provides a global estimate, because division and macrogroup types in the Americas are almost entirely restricted to the Americas, apart from the circum-Arctic types.

Adapted from Table 1 in Faber-Langendoen D, Baldwin K, Keeler-Wolf T, et al. (2018) The EcoVeg Approach in North America: U.S., Canadian, and International Vegetation Classifications. *Phytocoenologia* 48: 215–237.

Fine-scale types are only available in North America and parts of Latin America. Cultural types have only been developed at lower levels for North American forest plantations. Currently all macrogroup types in the Americas are listed in Faber-Langendoen et al. (2018) and are published on NatureServe Explorer (natureserve.org/explorer).

Despite the incompleteness of the IVC per se at mid and lower levels, there are opportunities for completing a global view of vegetation types across all scales through a collaborative effort with comparable classifications. In this section, we highlight a number of important national or continental efforts that have strong similarities to the IVC.

South America

In South America concepts for IVC group types are approximated through a crosswalk to the closely related “terrestrial ecological system” types developed by NatureServe (Josse et al., 2003; Faber-Langendoen et al., 2018). These terrestrial ecological systems are mid-scale types based on aggregating associations or local vegetation types using spatial-ecological relationships. These types can then be aggregated to the macrogroup scale. The approach to mapping these types corresponds to the process described for Africa (see below).

Bolivia

Bolivian types are being described using the EcoVeg approach. The full integration of the vegetation types proposed for Bolivia (Navarro, 2011) into the IVC system is well underway through a collaboration with NatureServe (Table 6).

Africa

Terrestrial ecosystems and vegetation of Africa were classified and mapped as part of a larger effort and global protocol (GEOSS, the Global Earth Observation System of Systems), which includes an activity to map terrestrial ecosystems of the earth in a standardized, robust, and practical manner, and at the finest possible spatial resolution (Sayre et al., 2013). To model the potential distribution of ecosystems, new continental datasets for several key physical environment data layers (including coastline, landforms, surficial lithology, and bioclimate) were developed at spatial and classification resolutions finer than existing similar data layers. Multi-scale ecosystems were classified and mapped using the IVC in an increasingly detailed hierarchical framework, from class, subclass, formation, and division to macrogroup. A total of 157 macrogroup types were mapped, each with multiple, repeating occurrences on the landscape.

Europe

Europe has a long tradition of vegetation classification using the “Braun-Blanquet approach” (Westhoff and van der Maarel, 1973). In an effort to harmonize the many national and regional classifications developed over the last century, the IAVS Working Group European Vegetation Survey established the “European Vegetation Classification Committee” to maintain and update a standard classification of European vegetation, taking the “EuroVegChecklist” (Mucina et al., 2016) as a baseline (<http://euroveg.org/evc-committee>). This standard classification includes the phytosociological class, order and alliance level. A harmonization with the

Table 6 Application of International Vegetation Classification to Bolivian forest and xeromorphic woodland vegetation (Navarro, 2011).

A provisional assignment of Braun-Blanquet classes ([Mucina et al., 2016](#)) is made to draft division units and grouped into IVC formation (Wolfgang Willner). In the European tradition, vegetation dominated by medium or tall shrubs with cover >25% (typically >60%), as well as krummholz, is included in the Forest and Woodland formations. In fact, they are not even separated at the class (macrogroup) level in many cases.

upper and middle levels of the IVC seems feasible but has not been done so far (See example in [Table 7](#)). In accordance with the phytosociological tradition, cultural vegetation in the strict sense is not considered in the classification. However, spontaneous species assemblages in strongly anthropogenic habitats (e.g., weed communities in arable land) are included alongside natural and semi-natural vegetation, since these communities are mainly composed by species native in Europe and adjacent regions and have co-evolved with human agriculture since neolithic times.

China

The China Vegetation Classification System (China-VCS) was developed based on the “phytocoenological-ecological” approach dating back to 1960 ([Guo et al., 2018](#)). The main principles for vegetation classification include vegetation physiognomy and structure, dominant species, floristic composition, and environmental attributes. This classification system for natural/semi-natural vegetation has eight hierarchical levels: Association < Association-group < Subformation < Formation < Formation-group < Vegetation-subtype < Vegetation-type < Vegetation-type-group ([Table 8a](#); [Guo et al., 2018](#)). Compared with EcoVeg, both approaches use similar principles and criteria for the assignment of vegetation types, including major growth forms (physiognomy) and vegetation structure, species composition or floristics, and ecological context ([Guo et al., 2018](#); [Faber-Langendoen et al., 2018](#)). Physiognomy plays a predominant role at upper levels and floristics at lower levels in both classification systems. Floristic definitions of types at lower levels in the EcoVeg approach are based on “characteristic species combinations,” which include diagnostic, constant, and dominant species ([Faber-Langendoen et al., 2018](#)). However, lower levels in the China-VCS emphasize dominant species in multiple strata, based on species’ relative abundances (or importance values). The association, formation, and vegetation-subtype levels of the China-VCS are somewhat similar to the association, alliance, and division levels of

Table 8 The Chinese Vegetation Classification System and its relation to the International Vegetation Classification.

(a) Hierarchy level of China Vegetation Classification System

Levels	Units	Definitions	Examples
Upper	Vegetation-type-group	It is the uppermost unit and is defined based on the comprehensive ecological conditions and the physiognomy of vegetation. The unit generally reflects the main continental biomes (zonal vegetation) and the main azonal vegetation.	Forest
	Vegetation-type	It is the main upper class unit in the same vegetation-type-group, which is the assemblage of the plant communities with the dominant species in the dominant stratum sharing same or very similar life form (or growth form).	Deciduous needle leaved forest
	Vegetation-subtype	It is classified mainly based on the differences in ecological conditions of the same vegetation-type, e.g., altitude, temperature, substrates, and hydrologic conditions.	Cold temperate deciduous needle leaved forest
Middle	Formation-group	It is the assemblage of the formations, of which the dominants have very similar growth form and ecological habits and belong to the same taxonomic genus.	Larch forest (<i>Larix</i> forest)
	Formation	It is the main middle class unit under one vegetation-type or vegetation-subtype, which is the assemblage of the plant communities with the same dominant species in the dominant stratum.	<i>Larix gmelinii</i> forest
	Subformation	It is an auxiliary class unit below formation. Some species with wide ecological amplitudes may dominate in plant communities occurring in obviously different ecological habitats, but the difference is not large enough to assign the communities into different vegetation-types or vegetation-subtypes. It is not necessary for most formations to be classified into subformations.	–
Lower	Association-group	It is the assemblage of communities with the same dominant species in the dominant stratum and in a second stratum, which share similar structure and ecological conditions.	<i>Larix gmelinii</i> - <i>Ledum palustre</i> forest
	Association	It is the basic class unit, which is the assemblage of the communities with same or very close properties, such as the same dominants in all strata or synusiaes, very similar overall species composition and structure, and very similar ecological conditions.	<i>Larix gmelinii</i> - <i>Ledum palustre</i> - <i>Vaccinium vitis-idaea</i> - <i>Sphagnum squarrosum</i> forest

(b) Crosswalk Table for Chinese Vegetation Classification System and the International Vegetation Classification

China-VCS	IVC—EcoVeg
Vegetation-type-group	Formation class
Vegetation-type	Formation subclass
	Formation
Vegetation-subtype	Formation
	Division
Formation-group	Macrogroup
	Group
Formation	Alliance
Subformation	
Association-group	Association
Association	

EcoVeg, respectively (Table 8b). In the China-VCS, the formation is defined as “the assemblage of the plant communities with the same dominant species in the dominant stratum within one vegetation-type or vegetation-subtype” (Guo et al., 2018), while the higher-level classification is based on the dominant growth form and community physiognomy. To date, seven vegetation-type-groups, 40 vegetation-types and 93 vegetation-subtypes have been described in the China-VCS (Guo et al., 2018), while formations and associations are still not completely verified. Therefore, it is practical to use the IVC to describe regional biomes in China, with a crosswalk between China-VCS and EcoVeg.

Australia and New Zealand

Vegetation classifications and maps have been developed largely independently across eight Australian states and territories and New Zealand, due to historical legacies related to separate jurisdictional responsibilities for land management. Specht (1970) developed a factorial vegetation classification scheme with arbitrary quantitative thresholds based on dominant growth form, height and projective foliage cover of the tallest stratum, which became an important unifying influence on jurisdictional classification and mapping. Although a useful framework for mapping by remote sensing, its application to floristic classification was problematic due to structural variability of vegetation somewhat independent of floristic patterns. A variation of Specht's

scheme was subsequently used to attempt a synthesis within a National Vegetation Information System (NVIS), but jurisdictional inconsistencies in classification and spatial edge-matching have limited its usefulness. These are gradually being resolved, but the major groupings cut across natural ecological patterns. The most recent synthesis of Australian vegetation describes 16 physiognomically defined vegetation formations across the continent, with each of these resolved into a number of subclasses (Keith, 2017). Within an Australian context, many of these units are potentially referable to L3 (formation), L4 (division) and L5 (macrogroup) units of the IVC.

For New Zealand, Singers and Rogers (2014) define 140 terrestrial ecosystem units based on vegetation–biophysical relationships represented by dominant plant species, bioclimatic zones and azonal edaphic environments. These should be examined in relation to L4 (division) to L8 (association) levels of the IVC.

Applications of IVC for Conservation

We briefly note several recent applications of the IVC approach:

1. *Assessing ecosystems at risk*: There is a growing need for comprehensive approaches to assessing ecosystems at risk in order to address multiple levels of biodiversity in conservation planning and ecosystem services. A variety of methodologies have been developed in various nations and continents (e.g., NatureServe’s approach documented by Master et al., 2012), but the IUCN Red List of Ecosystem provides a global framework (Keith et al., 2013). Similarly, a number of ecosystem classifications can be used for red listing of terrestrial ecosystems, but the IVC typology provides guidance on a consistent scaling of those assessments. Current applications of ecosystem red listing in the Americas include a macrogroup scale assessment of all tropical and temperate forests across the Americas (Ferrer-Paris et al., 2018) and an ecological system assessment in temperate and tropical North America (Comer et al., 2020).
2. *Key Biodiversity Areas*: International conservation organizations have developed a methodology for identifying Key Biodiversity Areas (KBAs) (IUCN, 2016), including criteria for protection of at-risk ecosystems. In the KBA guidance, IVC macrogroups and equivalently units are noted as a suitable level for defining ecosystem types. When units such as these are categorized as “at-risk” through the Red List of Ecosystem process (see above), they can contribute to the identification of KBA sites.
3. *Analyses of protected status of regional ecosystem types*: As part of a “coarser filter” approach to protection of biodiversity, conservation planners seek to ensure that all major ecosystems are represented in protected areas. Belote et al. (2017) recently used the USNVC at the group scale and above to identify ecosystems that are currently under-represented in the existing protected area system. A comprehensive assessment of the current protection status of all macrogroups across the Americas has also been completed (Comer et al., 2020).

Conclusions

The basic structure of the IVC approach to classifying terrestrial biomes has strong similarities at the highest levels (IVC formation) to that of the Encyclopedia’s major sections (Table 9). The IVC develops a systematic approach to the full diversity of biomes around the globe, guided by large-scale patterns of vegetation, biogeography and ecology; whereas, the Encyclopedia takes more of an illustrative approach, listing the most prominent structural and biogeographic types. Because of its systematic approach, the IVC both describes the full range of ecosystems and contributes to systematic assessments of their rarity and protection status. But beyond the perspective of classification, the Encyclopedia provides a wide range of topics relevant to understanding how biomes function, including processes, threats, ecosystem services, animal life, and conservation, among others. Thus, the diversity of biome types provided by the IVC complements the diversity of biome topics provide in the Encyclopedia.

Table 9 Comparison of IVC formation class types (see also Table 4) and the major biome types used for the Encyclopedia.

<i>IVC formation class types</i>	<i>Encyclopedia: Major Sections</i>
1. Forest & Woodland	Forests
2.A. Tropical Grassland, Savanna & Shrubland	Grasslands and Shrublands
2.B. Temperate & Boreal Grassland & Shrubland	
3. Desert & Semi-Desert Vegetation	Deserts
4.A. Tropical High Montane Scrub & Grassland	Mountains (alpine systems)
4.B.1 Temperate & Boreal Alpine Dwarf-shrub & Grassland	
4.B.2. Polar Tundra & Barrens	Ice Sheets and Polar Deserts
5.B. Freshwater Aquatic Vegetation	Freshwater/Ponds
6. Open Rock Vegetation	—
7. Anthromorphic Vegetation	Anthromes
—	Islands and Atolls

Equivalencies are approximate.

Acknowledgments

The development of the IVC and the EcoVeg approach would not have been possible without support to the “Hierarchy Revisions Working Group” from the USNVC partners, namely, the Ecological Society of America Vegetation Classification Panel, NatureServe, and federal government agencies, especially the US Forest Service (lead agency and chair of FGDC), the US Geological Survey, the US National Park Service, and the US Bureau of Land Management.

Abstract

Of the Earth's three major biomes or realms, freshwater is the smallest, dwarfed in size and extent by terrestrial and marine realms. It has also been the most exposed to human exploitation, resulting in higher declines of biodiversity compared to other realms, primarily because of human reliance on fresh water and invasive species. Major sub-biomes in the freshwater realm can be grouped into seven categories: rivers and streams, lakes (salt, freshwater, oases and springs), palustrine wetlands (swamps, marshes, and floodplains), transitional waters (including estuarine and coastal lagoons), brackish tidal systems (deltas, intertidal forests, saltmarshes), subterranean water bodies and artificial wetlands (dams, rice paddies, aquaculture, canals and channels). A range of key freshwater characteristics, including the hydrological regime, water quality, and influences from terrestrial and marine drivers, form unique ecosystems around the world, providing for diverse species but ones which share many functional traits, reflected in convergent evolution. Direct or indirect appropriation of water resources (consumption, agriculture, and hydro-electricity) and disposal of waste water has devastated many of the world's freshwater ecosystems. Their protection demands identification of sustainable and cost-effective management of hydrological regimes and inflows, including protection and restoration of flows for the environment as well as management of invasive species, stopping habitat destruction and pollution.

Introduction

The freshwater realm is the smallest of the world's three major realms, but well behind terrestrial and marine realms in effective conservation management. Seasonal wetlands may only represent about 6% of the world's land surface but most of these (89%) are not in protected areas or identified as wetlands of international importance under the Ramsar Convention (Finlayson et al., 2011), recognized for their global importance (Reis et al., 2017). Ecosystems dependent on fresh water are also among the most biodiverse on Earth, providing habitats for many invertebrate, plant, fish, frog, reptile, bird and mammal species (Dudgeon et al., 2006). They are also critical for many terrestrial organisms which depend on water for drinking, dispersal and transport of nutrients (Kingsford et al., 2006). Their vulnerability to anthropogenic change primarily reflects humanity's fundamental dependence on these ecosystems for existence. Without fresh water, humans would not survive. These ecosystems provide many essential ecosystem services including drinking water, building materials, food, fiber, areas of significant cultural importance, and recreation (Mitsch and Gosselink, 2000; Kingsford et al., 2016). Despite relatively new technologies such as desalinization, most of our water still comes from surface or subsurface freshwater ecosystems. Unsurprisingly, we built many of our cities on the banks of rivers where there was a dependable supply of fresh water. This dependency has also made freshwater ecosystems among the world's most exploited, and consequently the most threatened (Dudgeon et al., 2006; Vörösmarty et al., 2010; Reis et al., 2017).

The freshwater realm extends well beyond the world's rivers and lakes to include floodplains, estuaries, saline lakes, coastal inlets, including fjords, and lagoons, springs and oases, geothermal springs, subterranean (e.g. karsts), and artificial ecosystems. All of these ecosystems are influenced by fresh water as a major driver, although this influence varies and interacts with other drivers to shape types of habitats and niches for different organisms. Ecosystems influenced by fresh water occur all over the world, in all biogeographic ecoregions, from the tundra, temperate areas, tropics, subtropics, and deserts (Olson et al., 2001; Abell et al., 2008).

There are freshwater ecosystems on the highest mountains and the lowest points in the landscape (e.g. Sea of Galilee, ~210 m below sea level).

The Biome concept has a long and versatile history in ecology. It has been adapted to diverse applications describing ecosystem functionality and biogeographical patterns, usually at large spatial scales (Mucina, 2019). The *Encyclopedia of the World's Biomes* recognizes freshwater environments as a single biome. Other applications of the concept recognize multiple biomes within the Freshwater realm. In this chapter, we follow IUCN's Global Ecosystem Typology (<https://iucnrle.org/about-rle/ongoing-initiatives/global-ecosystem-typology/>) to emphasize the diversity of ecological processes and biota across the full range of freshwater ecosystems. We recognize seven units (here termed "sub-biomes"), differentiated by major abiotic drivers that shape structure, function and composition. These sub-biomes are reasonably well established although often not explicitly linked to abiotic drivers (e.g. Kingsford et al., 2004). They include rivers and streams (lentic environments), lakes (freshwater lakes, salt lakes, springs, oases, geothermal springs), palustrine wetlands (floodplains or swamps), transitional wetlands (estuaries, coastal lagoons and inlets), brackish tidal systems (deltas, intertidal forests, saltmarshes), subterranean rivers and lakes and artificial ecosystems (e.g. dams, canals) (Table 1). Each of these sub-biomes is influenced by varying major abiotic drivers which determines their taxonomic structure and function. Importantly, these subbiomes are similarly structured around the world. Sometimes abiotic influences may vary. For example, temporary lakes in desert regions will vary considerably compared to permanent lakes in temperate regions of the world. Also, some lakes and rivers are affected by major seasonal changes such as freezing. But the major drivers will often be similar, varying in the type of hydrological regime (e.g. flow volume and frequency and duration of flooding).

There is one practical advantage to categorizing these freshwater-dependant sub-biomes in this way: the conservation management strategies are clear for reversing degradation processes as they are usually dependent on a particular abiotic factor (e.g. flow regime). Given available data, it is also possible to quantitatively determine their potential risk of collapse (Keith et al., 2013), allowing for regional and global assessments. This can prioritize a range of management options which extend from the local, regional, national and international. There are also a range of protection measures for ecosystems dependent on fresh water. Some of these are the same as for other realms, including protected areas and their management. Others are relevant to freshwater ecosystems include identification and legal designation of wetlands of international importance, under the Ramsar Convention, promoting wise use. Also, the scale of protection is critical, given that fresh water flows often originate high up in the catchment. There are also a range of international migratory bird agreements which focus on waterbirds dependent on ecosystems supplied by fresh water. These include flyway agreements and bilateral agreements. Most importantly for most freshwater ecosystems, there is a dependency on water management, often river management, required at the catchment or watershed scale, which includes management and protection of flow and flooding regimes.

In this chapter, we describe the major freshwater sub-biomes and their ecosystems, which depend on a unique hydrology and other interacting abiotic and biotic drivers that determine their particular structure, function and characteristic biota around the world. We also identify potential conservation management options for these complex ecosystems.

Different Freshwater Sub-Biomes

We describe each of the seven major freshwater sub-biomes separately, including different ecosystems categorized within each sub-biome (Table 1, Fig. 1), their distribution, major drivers, adapted biota and their threats.

Rivers and Streams

Rivers and streams carry water from upper catchments to join other rivers or flow out to sea or sometimes wetlands for endorheic river basins (Fig. 1, Table 1). As flowing bodies of fresh water, they are primarily defined by their linear structure, size and flow regimes, with a range of longitudinal, lateral and within river processes governing their ecology (Vannote et al., 1980; Junk et al., 1989; Thorp and Delong, 1994). Flow regimes depend on rainfall patterns in the stream catchment, which vary from year-round (e.g. Danube River, Sabie River, South Africa, Fig. 2) to seasonal (e.g. Tapi River, India) and episodic (Cooper Creek, Australia), as well as the geomorphology, position of a stream reach and size of the catchment (Table 1, Fig. 1). Africa's Nile River is the world's longest river at 6690 km, with a catchment area of 2.97 million km² while the Amazon River has the world's largest catchment area of >6.1 million km² (Holeman, 1968) and a river length of 6296 km (Holeman, 1968). Forty-six of the world's longest rivers are >2000 km and distributed across all continents (Holeman, 1968).

Rivers and streams can be separated into upland and lowland ecosystems (Fig. 1). Upland rivers and streams drain mountainous areas, with high topographic relief, at high rates of flow and provide for a range of habitats that reflect this, including rapids, riffles and waterfalls. Some rivers in the northern and southern hemisphere may freeze during the winter, limiting productivity and movements of organisms. Upland rivers drive high sediment and erosion processes when they flow, providing a range of ecological niches for organisms adapted to fast-flowing river environments, including micro-organisms, invertebrates, fish, reptiles (e.g. turtles) and some birds (e.g. dippers, *Cinclus* spp.).

Lowland rivers at low elevations with relatively simple topographic relief are usually much larger (width and depth) than their upland counterparts, carrying considerably larger volumes of water provided by a network of upland rivers and streams from upstream in the catchment. Lowland rivers generally have lower stream velocities, with increased turbidity (due to sediment) and higher temperatures than upland rivers. Their large size provides habitats for a range of small and large organisms including

Table 1 Major freshwater sub-biomes, their major abiotic drivers, characteristic biota and opportunities for conservation management. The sub-biomes described here are based on “biomes” defined within IUCN’s Global Ecosystem Typology (<https://iucnrl.org/about-rle/ongoing-initiatives/global-ecosystem-typology/>).

<i>Sub-biome</i>	<i>Description</i>	<i>Abiotic drivers</i>	<i>Characteristic biota</i>
Rivers and streams	Rivers and creeks which may be permanent, seasonal or intermittent, extending from mountains to the sea and including tributaries and distributaries, across all parts of the world. They can be separated into upland and lowland rivers, with perennial, seasonal or episodic flow regimes as well as some which go through a freeze-thaw cycle.	Flow is critical and varies with whether rivers are lowland or upland and climate (perennial, seasonal, episodic) resulting in significant variations in flow regimes. Turbidity and depth tend to be higher in lowland rivers and streams.	These vary depending on the flow regime and whether the river is upland or lowland. Upland biota are adapted to high flow rates and limited productivity while lowland biotic communities are often more complex, given the variety of different habitats. Where freezing affects rivers, biota are adapted to coping with these conditions.
Lakes	Salt and freshwater lakes which vary enormously in size, flooding regime (perennial, seasonal, episodic) and water quality (e.g. salt) across the world. Some also go through a freeze-thaw cycle. They also include small groundwater fed ecosystems such as springs and oases and geothermal springs.	Water is generally still but flooding regimes can be highly variable, with many lakes also affected by freezing. Area, depth, connectivity and water quality (e.g. salinity) all drive composition, structure and functions of lakes.	Biota are highly dependent on lake size and other drivers, with adaptations to flooding regime, salinity and freezing the most prominent, depending on the type of lake. Plants, invertebrates and vertebrates and other biota are adapted to these regimes.
Palustrine wetlands	These are distributed around the world and include floodplains, marshes, swamps, tropical and subtropical flooded and peat forests, bogs and fens. Variation is highly dependent on different flooding regimes, areas and structural complexity.	Flooding regime is critical, varying from permanent, seasonal to episodic, depending on the location of the wetland. Shallow depth and water quality as well as the size of the wetland are also primary drivers of complexity and type of system.	During wet phases, obligate aquatic organisms colonize these systems but they also support a wide range of amphibious plants and also terrestrial animals reliant on the productivity and drinking water, particularly in arid landscapes.
Transitional waters	Estuarine waters; permanent waters of estuaries and estuarine systems of deltas; intertidal marshes, includes salt-marshes, salt meadows, saltings, raised salt marshes, tidal brackish and freshwater marshes; intertidal forested wetlands, includes mangrove swamps, nipa swamps, tidal freshwater swamp forests and; brackish to saline lagoons and marshes with one or more relatively narrow connections with the sea.	These systems are determined by freshwater flow regime and their interaction with tidal systems. These are reflected in salinity, light, temperature and depth gradients. The variation in flow regimes	Biota are often adapted to brackish systems, sometimes with obligate parts of their life cycle tied to freshwater (e.g. fish breeding). The areas are important breeding sites for many organisms.
Brackish tidal systems	These include coastal deltas, intertidal forests and shrublands and coastal saltmarshes. They predominantly occur in the tropical regions of the world where there are significant freshwater ecosystems, including large rivers.	There is an interaction of freshwater inputs, tidal regime and terrestrial inputs in these systems. They interact in different ways to create spatio-temporal complex and dynamic, and often large ecosystems with many different niches. In particular, there is a strong salinity gradient reflecting these different drivers.	They support tidal forests, particularly mangroves and also saltmarshes. Depending on the size of these ecosystems they can support freshwater, marine and terrestrial organisms which can exploit the range of habitats created, across the different salinity gradients.
Subterranean rivers and wetlands	These include freshwater ecosystems underground or groundwater ecosystems. They include karst wetlands and cave systems as well as underground rivers.	Flow regime which may vary from lentic to lotic are important in determining characteristics of nutrient and flow processes as well as biotic interactions. Lack of light is the most important and determining factor. Low oxygen and scarce nutrients are also critical.	Organisms are generally adapted to the lack of light, with no eyes and lack of pigmentation (e.g. blind cave fish). They also have slow growth rates. Food-webs are truncated at the top, with few or no predators.

Table 1 Major freshwater sub-biomes, their major abiotic drivers, characteristic biota and opportunities for conservation management. The sub-biomes described here are based on “biomes” defined within IUCN’s Global Ecosystem Typology (<https://iucnrl.org/about-rle/ongoing-initiatives/global-ecosystem-typology/>).—cont’d

Sub-biome	Description	Abiotic drivers	Characteristic biota
Artificial wetlands	Water storage areas, including reservoirs, barrages, hydro-electric dams, impoundments; ponds, including farm ponds, stock ponds, small tanks; aquaculture ponds, fish ponds, shrimp ponds; salt exploitation, salt pans, salines; excavations; gravel pits, borrows pits, mining pools; wastewater treatment, including sewage farms, settling ponds, oxidation basins; irrigated land and irrigation channels, including rice fields, canals, ditches; seasonally flooded arable land, farm land and; canals, also includes water pipes and subterranean canals	Extreme variation in the hydrological regimes as well as nutrient loading, determined by the desired function, which in turn governs which species are able to exploit these systems.	Relatively low biodiversity, dependant on the hydrological character and physical attributes of structures. May offer refuge to species in times of low resource availability, namely droughts. Can influence transportation of individuals, assisting in colonization of both native and invasive species.

Fig. 1 Conceptual diagram of a river catchment, depicting rivers (R, upland and lowland) connecting a swamp (S) or floodplain, freshwater lake (FL) and estuary (E), with constructed dams (D) and isolated wetlands including springs (SP), salt lake (SL) and a swamp (S).

aquatic macrophytes, algae, plankton, waterbirds (e.g. waders, piscivores), reptiles (e.g. crocodiles) and mammals (e.g. otters, platypuses, dolphins).

Rivers and streams provide critical ecosystem services contributing to many global economies including agriculture, water supply, power generation, trade, transport and fisheries. Around the world 2 billion people rely directly on rivers for their drinking water, and 25% of the world’s food production depends on irrigation from rivers (Opperman et al., 2018). As a result of such major dependencies, rivers are threatened by related direct and indirect human activities. These include four major groups of threats: hydrological (water extraction, dams, changes to natural flow regimes, alteration of flooding regimes), physical (sediment extraction, channel alterations), pollution (water contamination, changes to water quality) and biological (loss/alteration to habitats, species’ invasions) (Dudgeon et al., 2006; Kingsford et al., 2016; Chiu et al., 2017). Climate change effects often compound these impacts (Balcombe et al., 2011).

Lakes

Lakes are enclosed still water areas, either freshwater or saline, found all over the world. They usually have inflowing and outflowing rivers or streams which maintain lake water levels. They vary enormously in size, depth, hydrological connectivity, permanence and water chemistry, reflecting their location and climate which drive flow and flooding regimes. Large permanent freshwater lakes (> 100 km²) are often connected to one or more rivers, with complex shorelines, varying depths and mosaics of habitat. Large

Fig. 2 Sabie River, a perennial river flowing through Kruger National Park, South Africa. Photo R.T. Kingsford.

permanent lakes are typically found in humid temperate and tropical regions, on large land masses (e.g. Great Lakes, North America, Lake Victoria, Africa, Qinghai Lake, China).

Similarly, small permanent freshwater lakes of up to 100 km² occur in humid temperate and tropical regions. They may be hydrologically isolated from streams or rivers, relying on local rainfall and small streams. Freeze-thaw freshwater lakes, predominantly in high latitudes and altitudes in the Northern Hemisphere and South America, freeze for at least 4–5 months of the year, over the late autumn, winter and early spring. During such periods, productivity is limited, given relatively poor exchange of nutrients, low flow and light combined with low temperatures. Small permanent lakes, which freeze, vary considerably in area and depth, and usually thaw in spring, increasing productivity for different organisms. Permanent lakes provide a perennial aquatic habitat which varies in relation to these seasonal drivers and inflows, providing habitats for a range of obligate aquatic organisms. This can lead to some of the world's most amazing biodiversity, with incredible examples of adaptive radiation (e.g. cichlid fish in Lake Malawi, (Albertson et al., 1999)). Lake Baikal in Russia is the deepest (~1.6 km) and holding the most water (23,000 km³) of any lake in the world, providing niches for more than 2660 animal and 1000 plant species (Timoshkin et al., 2016).

Artesian springs and oases are groundwater supplied wetlands, which are ecologically similar to small permanent lakes. They occur in dry, arid regions of southern Africa, the Sahara and Middle East, central Eurasia, southwest of North America and Australia. Their permanent water provides critical habitat for a range of biota, with high levels of endemism due to their hydrological isolation. Simple food webs are driven by autotrophs (e.g. aquatic algae and floating vascular plants) and macrophytes providing food for invertebrates (e.g. crustaceans, molluscs, arachnids, insects) and small-bodied fish. Geothermal pools and hot springs (e.g. Grand Prismatic Spring, Yellowstone National Park, USA, Fig. 3), mud pots and geysers also have their permanent water or moisture maintained by groundwater. Temperatures (>44 °C) are high and the water may be acidic (pH 2–4) or alkaline (pH 7–11) with high mineral content levels, resulting from the permanent interaction of groundwater with magma and hot igneous rocks. Geothermal pools occur in volcanically active areas at all latitudes. Their environments are hostile to most organisms and so they have low diversity of biota, which are highly specialized for extreme temperatures and water quality. They include bacteria and archaea, cyanobacteria, diatoms, filamentous algae, macrophytes and invertebrate detritivores (e.g. dipterans and coleopterans).

Seasonal freshwater lakes are typically small (<5 km²) and shallow (<1 m deep). Filling and drying patterns are driven by seasonal weather patterns of rainfall, inflow and evapotranspiration. They occur in sub-humid temperate and wet/dry tropical regions in monsoonal and Mediterranean climates where there are clear seasonal rainfall patterns. Where rainfall patterns are highly variable and episodic, there are many temporary freshwater lakes, filled by local rainfall, and episodic rivers and streams. They are shallow but may be large (>100 km²), occurring in semi-arid and arid regions of Africa, Americas, Asia and Australia. Seasonal freshwater lakes provide non-permanent wetland habitat for a range of biota that include those that are resident with coping strategies for dry periods (e.g. burrowing frogs (Lee and Mercer, 1967), zooplankton (Panarelli et al., 2008), and those that inhabit the wetland when water is available (e.g. fish (Kushlan, 1976) and waterbirds (Kingsford et al., 2010)).

Salt lakes receive flows from rivers or creeks but they seldom have outflows and so salts and minerals concentrate, as water evaporates. Permanent salt lakes can be large (>100 km²) and sometimes deep (>2 m). They are restricted to semi-arid climates, with high evaporation but reliable inflows, occurring in Africa, Eurasia (e.g. Caspian Sea) and western parts of North and South America (e.g. Great Salt Lake). Temporary salt lakes typically have short periods of inundation and long intervening dry periods in arid and

Fig. 3 Grand Prismatic Spring, geothermal pool in Yellowstone National Park, relies on high temperature groundwater. Photo K. Brandis.

semi-arid regions of Africa, Eurasia, Australia, North and South America. They can very large (e.g. Kati Thanda-Lake Eyre, Australia, 9500 km², Makgagikgadi Pan, Botswana, 4920 km²) and are typically shallow. High salinity of salt lakes and their temporary nature means they only provide habitat for specifically adapted organisms, although they can be highly productive. These organisms include specialized invertebrates (Williams, 1998) that can provide critical food resources for waterbirds (e.g. flamingos *Phoenicopterus* spp., Fig. 4) and Wilson's Phalaropes *Phalaropus tricolor*) (Senner et al., 2018).

Lakes also provide important ecosystem services to a range of human communities, including water for domestic, industrial and agricultural use, and food resources (Brönmark and Hansson, 2002) but this dependency also threatens lake ecosystems. Anthropogenic threats to lakes are similar to those affecting rivers, including alterations to flows, affecting inflows and outflows, pollution, infilling (land reclamation), invasive species and exploitation of resources (e.g. fish, waterbirds) (Kozhova and Silow, 1998; Brunsberg and Blomqvist, 2001; Senner et al., 2018). In addition to these threats, there are the pressures from increasing global populations and demands for freshwater and climate change impacts (Folke et al., 2004; Dudgeon et al., 2006).

Palustrine Wetlands

Palustrine wetlands are vegetated, non-riverine wetlands, moving between wet and dry phases, depending on the flooding regime. They are the interface between terrestrial and freshwater ecosystems and include tropical flooded forests and peat forests, subtropical/temperate forested wetlands, permanent marshes, seasonal floodplain marshes (Fig. 3), episodic arid floodplains, boreal, temperate and montane peat bogs, and boreal and temperate fens. They can be among the most extensive and biodiverse ecosystems on Earth, not only providing water for dependent organisms but also providing a source of high biodiversity, food and water for a large component of terrestrial biodiversity (e.g. Okavango Delta, Botswana, Fig. 5). They primarily occur where lowland rivers spread out across low elevation lands. Most large rivers have extensive floodplains, except where these have been developed, particularly in the Northern Hemisphere (Kingsford et al., 2016). Flooding regimes of these freshwater ecosystems are critical with the flood pulse providing the key input of productivity (Junk et al., 1989) but this can vary depending on the nature of river flows which supply these floodplains and are sometimes highly episodic and unpredictable (Walker et al., 1995).

Flooding regimes in these wetlands can vary from permanent shallow standing water or near-surface water tables, to seasonally high-water tables to episodic inundation with long inter-annual dry periods, dependent on highly variable flooding regimes of dryland rivers (Puckridge et al., 1998; Young and Kingsford, 2006). Filling of these wetlands can occur via episodic or seasonal high rainfall resulting in overbank river flows, or the maintenance of high-water tables providing abundant water through groundwater seeps or free-standing water (e.g. permanent marshes).

The availability of water plays a key role in determining productivity of these wetlands, often more productive compared to the surrounding landscape. Palustrine wetlands have complex food-web structures driven by primary producers such as zooplankton and macrophytes, supplying a range of high order vertebrates, including fish, birds, reptiles and mammal species. The productivity of these palustrine wetlands also make them important breeding sites for species such as waterbirds, some breeding in large colonies (Frederick and Ogden, 2001). The level of biodiversity and its responses largely depends on the size and complexity of the floodplain, swamp or forest.

Floodplain wetlands have supported large groups of people with their food and resources for building and maintaining settlements, including fish and reeds for buildings (Lemly et al., 2000). They also provide a plentiful supply of fresh water. In addition, congregation of terrestrial animals in such highly productive environments can also be a source of food for different communities and more recently for tourism. Many of the major wetlands of the world that attract high levels of tourism are large palustrine wetlands, including the Camargue (Europe), Florida Everglades (North America), Kakadu Wetlands (Australia), Mekong Delta (Asia), Okavango Delta (Africa, Fig. 5) and the Pantanal (South America, Fig. 6). Palustrine wetlands can also provide important ecosystem services through pollutant removal from water runoff (Reinelt and Horner, 1995).

Threats to palustrine wetlands include a wide range anthropogenic impacts: pollution, drainage and/or filling, conversion of use (e.g. to agricultural land, urbanization) (Reinelt et al., 1998), livestock grazing, water extraction, resource extraction (e.g. peat) (Graf

et al., 2012). These have impacted on the biota that rely on these wetlands, including alterations to vegetation (van der Valk, 2013), reduced taxonomic richness in invertebrates as a result of changes to water quality (Campbell et al., 2009), and reduced waterbird breeding (Kingsford and Thomas, 2004).

Transitional Waters

Transitional waters include many coastal ecosystems around the world, where the major drivers originate from both marine and freshwater sources, including riverine estuaries and bays, coastal inlets or fjords, and intermittently closed and open lagoons and lakes. Different tidal and freshwater regimes interact seasonally with geomorphology to create diverse niches which vary in salinity, light, depth and nutrient regimes for survival and recruitment of a wide range of adapted biota.

Estuaries and bays are the tidal mouths of rivers where marine and freshwater mix, distributed through the world, although rarely found on arid or polar coasts. Some are permanently open while others are intermittently open. Permanently open riverine estuaries and bays vary over time reflecting differences in geomorphology, freshwater inflows, tides and seasonality of climate. Estuaries support highly productive communities of arthropods, molluscs, fish, and birds (Alongi, 2009) and are often fringed by a mosaic of mangroves, salt marshes, intertidal areas and muddy and sandy shores. They support complex food-webs composed of planktonic and benthic invertebrates, fish, waterbirds, seabirds, mammals and reptiles.

Deepwater coastal inlets are glacier formed semi-confined aquatic systems open to oceans. They are found mainly at higher latitudes including along the coast of Alaska, Norway, Scotland, Denmark and Greenland but also in Chile, New Zealand and Antarctica. Norway's coastline is estimated to have 1200 fjords (Gregory, 1913). Freshwater inputs are predominantly seasonal when snow and ice melt. Deepwater coastal inlets are characteristically steep sided with deep water and limited light penetration. Fjords in Norway and New Zealand support deep-water coral reefs which are high in biodiversity (Hovland, 2008).

Intermittently closed and open lagoons and lakes are highly dynamic with their status changing with a combination of tidal ranges, freshwater inflow volumes, and sedimentation (McSweeney et al., 2018). An estimated 3% of the world's estuaries are intermittently open, mostly in Australian, South Africa and Mexico (McSweeney et al., 2017). Estuarine ecosystems, which constantly experience variations in environmental factors (e.g. salinity, dissolved oxygen, water depth), are typically characterized by a restricted number of species well adapted to the variable conditions (Pasquaud et al., 2015). These include tolerances to wide ranges in salinity e.g. fish (Whitfield et al., 1981), seagrass (Koch et al., 2007) and mangroves (Parida and Jha, 2010).

Transitional waters are declining at alarming rates around the world (Hopkinson et al., 2019), destroyed by onsite developments (Bilkovic and Roggero, 2008; Newton et al., 2014) and declining freshwater resources from the catchment. Diversions of freshwater inputs increase salinity, altering available niches to suit more saline-tolerant species (Schlacher and Wooldridge, 1996; Zampatti et al., 2010). The high productivity of transitional waters has made them a focus for human exploitation, particularly for food resources, driving their degradation around the world (McHugh, 1976). Urbanization and exploitation for aquaculture have also had significant impacts, driving long-term declines in biota. Global annual loss of mangroves areas is estimated to be 3–5 times greater than the global deforestation rate (Spalding, 2010), estimated at annual loss of 1.1% between 1990 and 2000 (FAO, 2017).

Brackish Tidal Systems

Brackish tidal sub-biomes are the intersection of marine, terrestrial and freshwater processes, forming unique, complex and highly productive taxonomic diversity and functions, sometimes over large areas (Triest et al., 2018). They include deltas, intertidal forests and shrublands and saltmarshes. River mouths represent dispersal points of river-derived sediments (Wright, 1977), driving the formation of deltas (e.g. Ganges–Brahmaputra, Nile, Yellow River deltas), continuously changing through interactions with fluvial, tidal and wave processes (Dalrymple et al., 1992), with varying degrees of dominance (Ellison, 2019), but also affected by terrestrial processes. River deltas comprise subaerial and subaqueous areas, the former extending along the delta plain into low-lying floodplains influenced by tidal and/or saline intrusions and the latter extending onto the continental shelf where unloading or nutrients and sedimentation occur (Bianchi and Allison, 2009). This complex mosaic and dynamic, over extensive areas, provides niches supporting high taxonomic and functional diversity for both resident and migratory species (Kelin et al., 2005; Barendregt et al., 2009; Campbell, 2012; Visser et al., 2019).

Many intertidal forests and shrublands include mangroves. These represent a diverse group of tropical tree species with physiological and morphological adaptations for intertidal environments, loosely zoned to seaward, central, and landward zones (Polidoro et al., 2014; Ellison, 2019). Globally, mangroves cover about 150,000 km², a third in the South East Asia (Spalding, 2010). Mangroves offer many services, including the protection of shorelines from erosion by providing a physical barrier to waves, enabling deposition, and building of peat (Gedan et al., 2011). Mangrove forests can be highly productive, supporting rich communities of arthropods, molluscs, fish, and birds (Alongi, 2009), with sesarmid and fiddler crabs functioning as key ecosystem engineers (Kristensen, 2008).

Coastal saltmarshes replace mangroves in mid to high latitudes, with an estimated global saltmarsh area at about 54,950 km² (Mcowen et al., 2017). They can be characterized as a subset category of tidal marshes (Daiber, 1986), defined by vegetated intertidal communities, dominated by herbs, grasses, and low shrubs bordering saline waters, subject to flooding by saline waters as a result of fluctuations in water levels in surrounding waterbodies (Adam, 1993). As a result, organic and inorganic resources from marine and terrestrial sources, they are among the highly productive ecosystems of the world. Species' richness of saltmarshes tends to increase from tropical to temperate latitudes (Bridgewater and Cresswell, 2003; Saintilan, 2009). Saltmarshes are dominated by benthic invertebrates, including snails, crabs and bivalves and offer important habitat for fish, including both resident and marine transient species (Visser et al., 2019). Saltmarshes also provide important habitat for many avian species for breeding, feeding and roosting (Spencer et al., 2009). Benthic algae and bacteria are prolific on sediments in associations with emergent vegetation, with distinct communities structured by biophysical attributes (Sullivan and Currin, 2002).

Brackish tidal systems have historically supported considerable human development (Day Jr et al., 2007; Renaud et al., 2013), continuing to provide critical ecosystem services (Vörösmarty et al., 2004; Bianchi and Allison, 2009; Hopkins et al., 2018). This has made them vulnerable to on-site exploitation as well as impacted by declining freshwater inputs and increasing pollution from riverine catchments. Many of the world's large deltaic systems are collapsing due to up-stream water resource developments which capture water, sediment, reducing accretion, and increasingly exacerbated by sea level rise (Blum and Roberts, 2009; Syvitski et al., 2009; Vörösmarty et al., 2009; Tessler et al., 2015). Deltaic areas provide extremely productive terrestrial and marine habitats and resources such as fishing, agriculture and livestock, driving extensive land conversion and degradation (Stanley and Warne, 1993; Memon, 2005; Li et al., 2017). There is also evidence that pollutants, including heavy metals are increasing in their concentration in some deltas (Fu et al., 2003; Bai et al., 2012).

Subterranean

Freshwater underground ecosystems or aquifers are extensive, paralleling and even surpassing freshwater surface ecosystems (Culver and Pipan, 2019). Subterranean water accounts for ~30% of global fresh water, compared to ~0.26% in lakes and reservoirs, with slow renewal rates of ~1400 years (Shiklomanov and Rodda, 2004). Underground streams and pools have few to limited internal sources of energy and nutrients, relying predominantly on surface connected streams for input (Culver and Pipan, 2019) and are heavily influenced by the geomorphology and surface climate. They have low biological productivity, devoid of photosynthesis and primary producers, dominated by heterotrophs (bacteria, archaea, fungi, and protista) (Culver and Pipan, 2019). The lack of light has resulted in a convergent evolution of species (troglomorphy) sharing morphological characteristics such as the lack of pigment and eyes, and elongated appendages with high levels of endemism (Pipan and Culver, 2012). Estimating the diversity of global subterranean species is difficult, with currently 20,000 described species of stygobionts and trogllobionts (Culver and Pipan, 2019). In more connected subterranean pools and rivers, transient vertebrates such as fish and salamanders may occur. In contrast, aquifers and hyporheic zones of saturated sediments beneath rivers and lakes, offer little connectivity with surface water, supporting a limited trophic structure, comprised almost exclusively of heterotrophic microbes and invertebrates (Gibert and Deharveng, 2002).

Aquifers hold 25 times more fresh water compared to above ground water in lakes and rivers (Shiklomanov and Rodda, 2004), making up to 98% of the earth's fresh water and providing the primary drinking water source between 1.5 and 3 billion people (Kundzewicz and Doell, 2009) and approximately 40% of global freshwater use for agriculture (Döll et al., 2012). Ground water also provide critical support for humans during periods of droughts (Castle et al., 2014). As a result, many of the world's ground-water ecosystems are under considerable pressure from extraction. In one assessment, 21 of the world's 37 largest aquifers were found to be depleted at unsustainable rates (Richey et al., 2015). More so, depletion of ground water and impoundment of fresh

waters by dams has significantly accelerated sea level rise (Wada et al., 2012), threatening billions of humans living in coastal regions. Groundwater ecosystems are also threatened by pollution, originating from mining activities (Lei et al., 2010; Shakoor et al., 2017), including fracking (Mooney, 2011).

Artificial Wetlands

Artificial wetlands, either entirely or partially modified human-engineered waterbodies, are ubiquitous around the world (Downing et al., 2006; Ellis and Ramankutty, 2008). They include large reservoirs (Fig. 7), ponds (e.g. small dams, sewage ponds, garden ponds, stormwater treatment ponds, and mining pits), rice paddies, freshwater aquaculture, artificial waterways, including surface and subterranean canals and pipes (Table 1). Large reservoirs (> 1–5 ha; (Biggs et al., 2017)) are formed by impounding river flows with dam walls (e.g. Hume Dam on the River Murray in Australia, Fig. 7), with 7320 recorded dams and associated reservoirs globally and a cumulative storage capacity of 6864 km³ around the world (Lehner et al., 2011). The ecology of reservoirs varies considerably, reflecting their uses for releases and diversions, and affected by geomorphology and upstream land uses, delivering nutrients, predominantly phosphorus and nitrogen, as well as suspended sediments (Bremigan et al., 2008). Primary productivity is generally low to moderate, restricted to the euphotic zone (limnetic and littoral zones), with relatively simple trophic networks. Species diversity is highest in the shallow littoral zones, supporting benthic algae, macroinvertebrates, fish, waterbirds, aquatic reptiles, aquatic macrophytes and terrestrial or amphibious vertebrates.

There are hundreds of millions of small artificial dams or ponds (Verpoorter et al., 2014) and estimated 16.7 million reservoirs (> 0.01 ha) with a storage capacity of > 8000 km³ (Lehner et al., 2011), making up 10–30% of global standing water area (Downing et al., 2006). Their productivity varies with nutrient profile and input, from extremely high in wastewater treatment ponds to very low in toxic mining and excavation pits, determining the taxonomic and functional biodiversity, mediated by connectivity to other waterbodies, vegetation and the catchment (Chester and Robson, 2013). Ecosystem function and diversity are also dependent on flooding and drying and depth but they can support a range of species including macrophytes, macroinvertebrates, crayfish, frogs, fish and waterbirds.

Rice paddies are a significant artificial freshwater aquatic ecosystem, making up as much as 12.3% of global crop area and 1.3% of global land area (1,982,841 km²), producing almost 9% of global food production (FAOSTAT, 2019), and accounting for 25%–33% of the world's developed freshwater resources (Bouman, 2009). They occur on transformed floodplains but also on terraced hillsides. Temporary waters combined with intensive management force simple trophic networks, dominated by cultivated macrophytes as well as other autotrophs but also supporting opportunistic species such as invertebrates, zooplankton, insects, frog, fish and waterbirds.

Fig. 7 Hume Dam on the River Murray in southeastern Australia, regulates flows in the river to provide water to agricultural communities (irrigation) and towns downstream, reducing flows to dependent wetlands and groundwater ecosystems. Photo R.T. Kingsford.

Related freshwater aquaculture ecosystems are also widespread. In 2017, 48.4 t of aquaculture production (43% of global production) was produced from freshwater habitats, including fish farms, ponds and tanks (FAO, 2019). Construction of freshwater aquafarms is accelerating (Ottinger et al., 2018; Ren et al., 2018) as global marine fish stock are depleting (Goldburg and Naylor, 2005), particularly through conversion of coastal wetlands, lakes and lagoons. Freshwater aquaculture is heavily dependent on external inputs of feed, energy and chemicals for sustaining primarily fish or crustaceans, affecting water quality and quantity in connected habitats (Troell et al., 2014; Ottinger et al., 2016). These freshwater aquaculture ecosystems support a simple trophic structure, with few non-target primary producers and secondary consumers, including some amphibian and bird species (Kloskowski and Nieoczym, 2015).

Linear artificial waterways are globally ubiquitous, including channels for navigation, flood protection (including stormwater drains), and irrigation canals or ditches. Channelized waterways exceed 500,000 km while constructed canals extend for 63,000 km (Gleick et al., 2001). In the United States agricultural lands, ditches occupy > 112,000 km² (U.S. Department of Agriculture, 2018), more than 300,000 km in the Netherlands (Verdonshot et al., 2012) and about 600,000 km in the United Kingdom, significantly larger than the total stream network (Maltby et al., 2011). There are also artificial subterranean canals and water pipes throughout the world. For supply of drinking and irrigation water, rapid flow rates and turbulence dominate waters that are generally low in nutrients, with development of microbial biofilms on internal pipe surfaces (Douterelo et al., 2013). Contrastingly, urban stormwater and sewage pipes and canals have relatively slower flows with low turbulence and low water quality, given high levels of contaminants (Nilsen et al., 2019). The functions and biota of these artificial waterways are highly variable and dependent on flow, sediment base, substrate, and catchment scale inputs (Meybeck, 2003; Chester and Robson, 2013; Biggs et al., 2017). They generally have low taxonomic biodiversity with simple functional relationships, although can sometimes providing refuge, breeding grounds, and dispersal routes between habitats (Chester and Robson, 2013; Harvolk et al., 2014; Biggs et al., 2017).

Clearly these artificial freshwater ecosystems are established primarily to provide ecosystem services in the form of drinking water, water for agriculture, generation of hydroelectricity as well as providing food and fiber. But nearly all threaten natural freshwater ecosystems principally by removing or fundamentally changing the hydrological regime which sustains these natural ecosystems (Kingsford, 2000). When not managed well, degradation ensues, including destruction of habitat, loss of productivity from agricultural areas, with increasing salinity and pollution. Other examples include low level flooding of rice paddies which can produce anoxic soil conditions and emissions by methanogenic archaea, accounting for more than 10% of total methane flux in the atmosphere (Ehhalt et al., 2001; Sass and Cicerone, 2002) as well as increased transmission of diseases such as the avian influenza virus (Gilbert et al., 2017). Also, fish farms are generally considered detrimental to native fish biodiversity when released into natural freshwater habitats (Bezerra et al., 2019) as well as depleting native fish stocks for fish feed (Goldburg and Naylor, 2005).

Conservation Management

Direct and indirect human development has destroyed or degraded many of the world's freshwater ecosystems, well over half and up to 90% in some regions of the world (Junk et al., 2013; Davidson, 2014). Extensive natural freshwater ecosystems have disappeared and continue to be destroyed with ongoing appropriation of freshwater resources for human communities. This makes conservation management particularly challenging, given increasing human population growth and so much of our food, fiber and building materials dependent on use of fresh water. Until this fundamental challenge is appropriately addressed by reducing human demand on freshwater resources, the freshwater biome will continue to degrade and more water dependent species will be lost and many of those terrestrial species dependent on fresh water. There will also be significant impacts on dependent ecosystem services. As well, the human footprint in terms of establishing urban communities has destroyed many freshwater ecosystems around the world. For example, 10.9% of estimated global population resided in low-elevation coastal zone in 2000 (Neumann et al., 2015), resulting in destruction of many coastal ecosystems. In addition, establishment of large-scale agriculture also continues to destroy many freshwater ecosystems around the world (Zhang et al., 2010).

There are some critical measures which must be taken to halt the loss of freshwater ecosystems due to human activities around the world. These include focusing on the demand for fresh water and limiting the human footprint, particularly urban, mining and agricultural, on natural freshwater ecosystems (Butler et al., 2015; Dodds, 2019). Demand for appropriation of more fresh water can only be met through recycling of water in large urban communities, improved capture and use of water within urban communities, and desalination (Vörösmarty et al., 2010). Further, there is an urgent need to improve efficiencies with which irrigated plants receive water so that the impact on diverting water from surface and groundwater freshwater ecosystems is reduced (Howell, 2001; De Pascale et al., 2011). This does not mean increasing the area of irrigation but rather making the most of the water currently diverted and even allowing for returning water to freshwater ecosystems for restoration. In addition, further destruction of freshwater ecosystems by urbanization, mining and agriculture must be avoided. Such measures require political will (Chhatre and Saberwal, 2005), only accomplished through public discourse and knowledge (Cooke et al., 2013), which also needs to be founded on an improved understanding of the scale of loss of freshwater ecosystems and our dependencies on these systems for ecosystem services.

There are a range of policy and management mechanisms which are important for implementing improved conservation management of freshwater ecosystems (Amezaga et al., 2002; Kim, 2010; Clare and Creed, 2014). The traditional conservation approaches primarily hinge on protection of areas of freshwater ecosystems (Saunders et al., 2002). These primarily focus on the primary approach of gazetted and management of freshwater areas as protected areas within National Parks or other reserves.

Similarly, identification of such areas as wetlands of international importance under the Ramsar Convention represents a similar approach where areas of land including important freshwater ecosystems are identified and there is a focus on their sustainable management (Gardner and Davidson, 2011). Unfortunately, such management may not be effective unless there is a strong focus on also protecting the flow and flooding regimes to these systems. This primarily means stopping further loss of the sustaining flow and flooding regimes which are often impacted by diversions of water to urban communities or irrigated agriculture. Until both the area of the freshwater ecosystem and its supply of water are protected, there will be inadequate long-term conservation management.

There are also a range of broad policies related to protecting specific aquatic animals and plants which may be threatened by extinction (i.e., IUCN Red-listed species) (Rodrigues et al., 2006). These may address the protection of fresh water inflows. There are also various migratory species agreements which are critical for long-term conservation of different species, particularly bird species (Runge et al., 2014; Runge et al., 2017). Long term protection fundamentally relies on protection of habitats from human incursions around the world (Murray et al., 2014; Murray and Fuller, 2015).

Restoration of freshwater ecosystems can occur with a focus on restoring flows and natural flooding regimes. This may not only mean protection of the current flows but also restoration of more flows, sometimes termed environmental flows (Arthington, 2012; Acreman et al., 2014). These also inevitably need to be managed to determine the range of influences on long-term trajectories of restoration for the ecosystems and overall effectiveness (Thompson et al., 2018).

Conclusions

There are a range of diverse natural freshwater ecosystems in the freshwater realm, dependent on unique hydrological regimes. These include rivers and streams, lakes (freshwater and salt lakes, oases, springs, and ponds), palustrine wetlands (floodplains, swamps and marshes) transitional waters (coastal inlets and fjords and estuaries), brackish tidal systems (deltas, intertidal forests and shrublands, saltmarshes) and subterranean freshwater ecosystems. These provide a tremendous diversity of habitats and make up some of the Earth's most spectacular ecosystems for biodiversity. Unfortunately, much of this diversity has been lost over human history, largely because of our dependence on fresh water for our livelihoods, directly for drinking but also for much of our food, fiber, energy and building. The freshwater realm and the different sub-biomes and ecosystems are under increasing pressure, driving high rates of loss of freshwater ecosystems, their species and the essential ecosystem services they support. Management at the catchment scale is important, focusing on the protection of natural flow and flooding regimes. The dire status of freshwater ecosystems will not change without significant alteration of human behaviour in terms of reducing demand on freshwater resources and protecting these important habitats.

Abstract

As the source providing units for several goods and services required for human survival (e.g. food, fuel, fiber, water provision and purification, etc.) ecosystems must be sustainably managed. This will require a globally comprehensive and detailed understanding of the distribution of ecosystems on Earth. While there have been several attempts to partition the planet into large ecologically meaningful areas (ecoregions), a high spatial resolution map of Earth's terrestrial ecosystems at the on-the-ground occurrences (patch) level has heretofore been lacking. A new, high resolution (250 m) map of data-derived World Terrestrial Ecosystems is characterized, and its utility for assessing policy-mandated ecosystem conservation targets is described.

There are many controlling influences which determine the distribution of species on the planet, including environmental heterogeneity (e.g. climate and geomorphology), evolutionary history, species relationships, dispersal dynamics, and the history and spatial patterns of natural and human-caused environmental disturbances. With a focus on understanding these drivers, biogeography is broadly understood as the study of why species are distributed where they are, a question which was of interest to Charles Darwin and Alfred Russel Wallace in the mid-1800s. Ecosystems geography is a similar but newer discipline that focuses on where ecosystems occur, and the drivers that control their distributions (Bailey, 2009). Ecosystems are understood as biological communities interacting with each other and with their physical environment (Odum 1953) and have been defined and mapped from a variety of perspectives related to both structural (e.g. canopy structure) and functional (e.g. photosynthesis) properties. Zhao and Costello (this volume) define ecosystems as enduring, spatially bounded environments where biological relationships (e.g. trophic levels) and energy interactions (e.g. evapotranspiration) are more similar within than with other ecosystems.

Ecosystems are multiscalar, and have been mapped at a variety of scales ranging from local to global. Common geographies for which ecosystem maps are developed include sites, nations, regions (including ecoregions), continents, and the planet. Terrestrial ecoregions are understood as macro-scale ecosystems and are defined as "relatively large units of land containing a distinct assemblage of natural communities and species" (Olson et al., 2001).

Understanding the distributions and condition of Earth's ecosystems is increasingly important as they provide humans with a number of goods and services (e.g. food, fiber, fuel, water quality and quantity, carbon sequestration, flood control, etc.) necessary for our survival. In order to continue providing these services, ecosystems need to be well-managed, and for many "endangered" ecosystems (Keith et al., 2013) a conservation focus is encouraged. The importance of conserving ecosystems is reflected in two major intergovernmental policy instruments: (1) Aichi Target 11, which establishes a 17% protection goal for all terrestrial ecosystems on the planet (www.cbd.int/sp/targets/), and (2) the UN Sustainable Development Goals (SDGs, and in particular SDG 6 (freshwater), SDG 14 (coastal and marine) and SDG 15 (terrestrial)) which call for the conservation of Earth's ecosystems (<https://sustainabledevelopment.un.org/sdgs>). A map of the distribution of these ecosystems and an analysis of their conservation status is essential for understanding progress toward these goals.

Given the importance of knowing what ecosystems exist on the planet, where they are located, and what condition they are in, a standardized (reproducible), data-derived, globally comprehensive, and high spatial resolution map of the distribution of earth's ecosystems is needed. Existing ecoregion maps (e.g. Bailey, 2009; Dinerstein et al., 2017) generally describe large, ecologically meaningful areas, and are often used in global conservation priority setting analyses. These ecoregion-scale maps do not, however, characterize the on-the-ground distributions of finer scale terrestrial ecosystems at the occurrence level.

A new map of World Terrestrial Ecosystems (Sayre et al., 2020) was recently produced at a 250 m spatial resolution based on an integration of climate regime, landforms, and vegetation/land cover. The map was developed using United Nations Food and Agriculture Organization (FAO) and Intergovernmental Panel on Climate Change (IPCC) criteria for ecological zones and climate regions. The World Terrestrial Ecosystems are depicted in Fig. 1. A legend block for the World Terrestrial Ecosystems is included in Fig. 2.

The World Terrestrial Ecosystems were developed from a spatial integration of several input layers. A World Temperature Domains (Polar, Boreal, Cool Temperate, Warm Temperate, Subtropical, and Tropical) layer was developed by analyzing

Fig. 1 World Terrestrial Ecosystems mapped at a 250 m spatial resolution. There are 431 ecosystems at the globally aggregated level, and 1778 ecosystems when segregated by biogeographic realms (Nearctic, Neotropical, Palearctic, Afrotropical, Indomalayan, Australasian, Oceania). Each ecosystem is a unique combination of climate regime, landform type, and vegetation assemblage/land cover. From Sayre R, Karagulle D, Frye C, Boucher T, Wolff N, Breyer S, Wright D, Martin M, Butler K, Van Graafeiland K, Touval J, Sotomayor L, McGowan J, Game E, and Possingham H (2020) An assessment of the representation of ecosystems in global protected areas using new maps of World Climate Regions and World Ecosystems. *Global Ecology and Conservation* 21(2020): e00860. <https://doi.org/10.1016/j.gecco.2019.e00860>.

temperature data from thousands of meteorological stations over a 30-year record of observations. A World Moisture Domains layer (Moist, Dry, and Desertic) was similarly developed from precipitation observations. The World Temperature Domains (6) layer was integrated with the World Moisture Domains (3) layer to produce 18 World Climate Regions. The 18 World Climate Regions were then unioned with a World Landforms (Plains, Hills, Mountains, and Tablelands) layer to produce a 72 class integrated climate/terrain layer. Finally, the 72 climate/terrain classes were integrated with a World Vegetation/Landcover layer (Forestlands, Shrublands, Grasslands, Bare Areas, Croplands, Water, Snow and Ice, and Settlements). The combination of 72 climate/terrain types with 8 vegetation/land cover types produces 576 possible combinations of World Terrestrial Ecosystems, of which 431 were realized (e.g. while tropical moist plains with snow and ice is a possible combination, it does not exist). The full methodological details and input layer descriptions are found in Sayre et al. (2020).

The conservation status of the World Terrestrial Ecosystems has also been identified from a global gap analysis of the representation of the ecosystems in protected areas. The gap analysis was an evaluation of the area of each ecosystem which was contained within a protected area in order to assess the ecosystem's conservation status against a protection goal (gap in protection). The gap analysis was conducted using all protected areas from the World Database on Protected Areas (WDPA; <https://www.protectedplanet.net>). The gap analysis was repeated using a subset of the WDPA polygons with only IUCN management category I-IV included to emphasize only those parks with a strict conservation management focus. As would be expected, using all protected areas in the gap analysis resulted in relatively increased conservation status for many ecosystems. However, when considering only strictly conserved protected areas (IUCN management category I-IV), few ecosystems approach the 17% protection goal as specified in Aichi Target 11 (www.cbd.int/sp/targets/). The true management effectiveness of all protected areas is still unknown, and until it is known, gap analyses based on IUCN management category and other criteria are best understood as approximations in need of refinement. More details on the gap analysis methods and results are found in Sayre et al. (2020).

The new World Terrestrial Ecosystems represent a mapping of the unique combinations of climate regime, landform and major vegetation assemblages/land cover types. As such they represent an ecosystem structure-based mapping approach, i.e. they are derived from a mapping and subsequent integration of the major abiotic and biotic structural elements of ecosystems. We recognize that there are other approaches to conceptualizing and mapping terrestrial ecosystems based on their functional properties (e.g. nutrient cycling, trophic relationships, etc.), but a globally comprehensive, high resolution, data-derived map of ecosystems based on most ecosystem functional properties does not yet exist (although productivity is a notable exception). A classification (list and description) of global ecosystems based on functional properties is in development by the IUCN Red List of Ecosystems community (Keith et al., 2013).

Faber-Langendoen et al. (this volume) describe global vegetation assemblages based on considerations of vegetation physiognomy (structure) and composition. The World Terrestrial Ecosystems resource is not a vegetation classification, but it does

Fig. 2 Legend block for the map of World Terrestrial Ecosystems in Fig. 1, above. This graphic describes the color assignments for the 431 ecosystems. The legend block is not intended for distinguishing between similar ecosystems, which would have similar color assignments. Rather, the legend block is intended to allow users to understand ecosystems as all possible combinations that result from the combination of the climate regions (temperature and moisture), landform type, and vegetation assemblage/land cover type. From Sayre R, Karagulle D, Frye C, Boucher T, Wolff N, Breyer S, Wright D, Martin M, Butler K, Van Graafeiland K, Touval J, Sotomayor L, McGowan J, Game E, and Possingham H (2020) An assessment of the representation of ecosystems in global protected areas using new maps of World Climate Regions and World Ecosystems. *Global Ecology and Conservation* 21(2020): e00860. <https://doi.org/10.1016/j.gecco.2019.e00860>.

incorporate a biome-level vegetation assemblage classifier (i.e. forestlands, shrublands, grasslands, and sparsely- or non-vegetated natural areas), reporting either non-vegetated natural land cover (water, snow and ice) or converted land cover types (croplands, settlements) where natural vegetation is lacking. An assessment of the conceptual and spatial concordance between the EcoVeg units (Faber-Langendoen et al., this volume) and the World Terrestrial Ecosystems (Sayre et al., 2020) would be interesting and is encouraged along the lines of future work.

In conclusion, terrestrial ecosystems have been rigorously mapped from data at a 250 m spatial resolution based on climate, landform, and vegetation. This new characterization supports an understanding of the types and locations of the terrestrial ecosystems on Earth. Such an understanding is required to assess progress toward Aichi and SDG ecosystem conservation targets. The resource is intended to be useful for other applications as well, including ecosystem valuation and accounting, ecosystem-based inventory and management, and greenhouse gas modeling.

Summary of the Section's Papers	36
Summary	45
References	45

Abstract

The Islands and Atolls Section of the Encyclopedia of the World's Biomes covers unique examples of islands, atolls, and archipelagos across the world. The section is unique in that it contains all of the physical and biological elements traditionally described as biomes in other sections, plus aspects of island biogeography. The papers in the Islands and Atolls Section represent a broad mix of island biogeography, ecology, conservation, and management.

Overview—Islands and Atolls

The Encyclopedia of the World's Biomes takes a broad look at the Earth's biogeographic zones, roughly broken into water, land, and human systems. Water includes oceans (one blue planet), freshwater (the oasis of life), ice sheets and polar deserts (ice of life), and islands and atolls (life in and surrounded by water). Terrestrial includes deserts (life in the extremes), forests (trees of life), and shrublands and grasslands (sea of plants). Human systems includes the geographic distribution of anthromes as well as the sustainable stewardship of the anthrome biosphere. This piece on anthromes helps tie together this work with our previous Encyclopedia of the Anthropocene ([DellaSala and Goldstein, 2018](#)). It also helps us think about the imperiled ecosystems and species of the world.

The Islands and Atolls Section does not follow traditional biome nomenclature. We realize it is unusual to hear that *Islands* are a biome unto themselves. We do not want that to be confusing. An *Island Biome*, while different than the traditional delineation of a biome, is distinct because it delivers to the reader an overview of the uniqueness of islands, atolls, and archipelagos across the world. The section roughly breaks out into an overview of the islands and atolls of the world, a revisit of the theory of island biogeography, a look at some interesting and unique regional examples, and aspects of development, management, and conservation.

Summary of the Section's Papers

The section begins with an overview of global islands (Sayre et al., 2018; Martin et al., 2020). This paper displays a new map (Fig. 1) of the islands of the world using high resolution satellite imagery, classifying islands as continental mainland, islands $> 1 \text{ km}^2$, and islands $< 1 \text{ km}^2$ (Table 1). The new high-resolution islands data are intended to support coastal ecosystem mapping efforts and assessments of threatened island biodiversity, among other applications. This chapter summarizes the global island mapping approach and results and provides a new perspective on the size distribution of the islands, atolls, and archipelagos of the world.

Helmus and Behm (2020) discuss how island biogeography is determined by three processes: immigration, evolution, and extinction (Fig. 2). They further discuss how human impacts have become increasingly more important to island biogeography through human population expansion, species introductions resulting in rapid evolutionary change to native island species, and subsequent island extinctions.

Warren et al. (2020) provides links between the Theory of Island Biogeography and other key theories in ecology. They include modifications to “Core” Island Biogeography Theory and show the role the Theory plays in inspiring other quantitative theories that are at least as broad in relevance. The Island Biome, or islands surrounded by water is an obvious choice to study the effects of area and isolation on species richness. Island boundaries frequently provide longstanding limits to the distributions of species or populations. As discussed by Warren et al. (2020), and as we see in other papers in this section (Hawaii, for example, as summarized by Kim et al., 2020), islands provide particularly striking examples of rapid change in selection gradients following the arrival of new immigrants.

Through the perspective of shallow-water organisms, Hachich et al. (2020) explored island biogeography in the marine realm. Their goal was to provide an overview of processes and patterns related to marine shallow-water island biogeography. They formulated predictions of expected functional island biogeography patterns, regarding the effects of environmental filtering, selective extinction or neutral mechanisms. When put together, the data show patterns of speciation and endemism in marine shallow-water organisms in oceanic islands. For example, patterns of neo and paleo-endemism of reef fish are plotted in a global map (Fig. 3), and variations of marine shallow-water endemism with islands age, area, and isolation are shown for reef fishes and marine gastropods (Fig. 4).

Miller (2020) provides an overview of the social, ecologic, and economic impacts of sea level rise, a topic that is discussed across this section. Global sea level rise disproportionately effects the livelihood and ecosystem health of the nations and people residing on islands and atolls. Islands and atolls of the Western Pacific are the most threatened due to regional intensities of sea level rise, increasing intensity of storm events with associated storm surge, vulnerability of coral-based islands to erosion, and genetic and species vulnerability of biological communities due to their relative isolation (Fig. 5). The increasing loss of islands and atolls has resulted in an imminent loss of island cultures, species extinctions and ecosystems. Murry et al. (2020) show future scenarios in the Caribbean based on the combination of drought and sea level rise (Fig. 6).

Mitigating the effects of sea level rise are discussed, both from the global and local perspective, and suggest global mitigation actions will require a profound shift in the way we live over the next 100 years. Communities are considering options including

Fig. 1 Map of global islands (Sayre et al., 2018; Martin et al., 2020). Continental mainlands are depicted in brown, islands bigger than 1 km^2 (big islands) are depicted in green, and islands smaller than 1 km^2 (small islands) are depicted in red. Small islands, not visible at this coarse resolution and page size have been rendered visible through visual exaggeration using increased point sizes for feature symbols.

Table 1 Number, area, and coastline length for islands in three size classes (Sayre et al., 2018; Martin et al., 2020).

Landmass type	Number of polygons	Area (km ²)	Length of coastline (km)
Continental mainlands	5	125,129,046	813,467
Big Islands > 1 km ²	21,818	9,938,964	1,304,762
Small Islands ≤ 1 km ²	318,868	20,589	321,774

Fig. 2 Island biodiversity is determined by three fundamental biogeographic processes: immigration, evolution, and extinction (Helmus and Behm, 2020). These three processes vary with island area and isolation from source pools of immigrants. Arrows depict the relationship direction in these three processes, which vary with island area and isolation from source pools of immigrants.

Fig. 3 The proportion of reef fish endemic species found in different oceanic islands across the marine biogeography regions. Circle sizes indicate the proportion of the assemblage made up by endemic species. Colors show the different types of endemism (neo or paleo) observed in oceanic islands (Hachich et al., 2020).

Fig. 4 The variation of marine shallow-water endemism with islands (A) age, (B) area and (C) isolation for reef fish and marine gastropod. Only significant ($p < 0.05$) regression lines are presented (Hachich et al., 2020).

Fig. 5 Sea level rise in the Solomon Islands in combination with increasing storm surge has made communities and ecosystems highly vulnerable to erosion and inundation (Miller, 2020) (from <https://www.newstalk.com/news/as-sea-levels-rise-in-the-pacific-five-of-the-solomon-islands-have-disappeared-598805>, accessed 20 January 2020).

Fig. 6 Current projections in the Caribbean, for example, highlight extensive drought, extreme sea level rise, and more frequent and intense hurricanes. Four potential future scenarios are shown for the Caribbean, based on low to high sea level rise and small to large increases in drought (Murry et al., 2020).

building walls, moving to higher ground, and transfer off island to higher mainland areas. As sea water intrudes, area is lost or inhabitable and emigration must occur. The loss of heritage and culture is happening within a human lifetime.

The archipelagos of the high Arctic (Fig. 7) are some of the remotest places on Earth, where climates are extreme and change only slowly, given the dynamics of the Arctic Ocean. Gaston (2020) describes the physical biogeography of the Arctic islands and how these islands are home to specialized Arctic plants and animals, characteristic of the Pleistocene period, many of which will be severely challenged by global warming. They are likely to provide the last refugia for many High Arctic endemics, such as gyrfalcon (*Falco rusticolus*) and muskox (*Ovibos moschatus*), as well as many Pleistocene plants. Consequently, colonization by low Arctic and Boreal species may adversely impact many of these species.

Isolated in the North Atlantic Ocean, the Azores Islands are home to a unique biodiversity. Land-use changes, fragmentation, the introduction of exotic invasive species and climate change all act to threaten the persistence of species on these islands (Fig. 8). Effective conservation strategies should be based on a deep knowledge of species abundance, trends, and distributions, that can be obtained from long term monitoring schemes like the ones implemented there (Borges et al., 2020).

Gould et al. (2020) and Murry et al. (2020) each tackle aspects of climate change in the Caribbean. Gould describes the importance of coastal areas to the economic, cultural, and natural resource base of island societies, noting that sea level rise, storm surge, and the salinization of coastal soils have tremendous consequences to consider when planning for the future. Green infrastructure

Fig. 7 Islands of the Canadian Arctic Archipelago (Gaston, 2020).

Fig. 8 The mosaic of human modified habitats at mid and low elevation (Terceira Island, Azores), with dominance of pastures for cattle grazing, surrounded by the exotic tree species, *Cryptomeria japonica*. Photo credit: P.A.V. Borges.

Fig. 9 Known locally as Elfin Woodland, these cloud forests in the Luquillo Mountains of Northeastern Puerto Rico lie within the El Yunque National Forest and Luquillo Experimental Forests. They harbor a high percentage of endemic species across many taxonomic groups (Gould et al., 2020). Photo credit: G. González.

can play an important role as both a buffer to sea level changes and a resource and habitat for wildlife. Habitat protection for rare and endemic species in the Caribbean is particularly important as the cloud forests of the upper mountains because the highest concentration of endemics, are also most vulnerable to a warming and drying climate (Fig. 9).

Murry et al. (2020) details how cays and islets can provide habitat and safe haven from anthropogenic impacts for many species of concern including many resident and migratory seabirds, shorebirds, endemic reptiles, and plants. The challenge, they contend, is that management is limited by insufficient resources, capacity, and a mixture of ownership (US Federal, Commonwealth, Territorial, non-profit organizations, and private), making regional planning a challenge (e.g., Fig. 10). Like most island systems, the dominant short- and long-term threats are invasive species. In addition, recreational and commercial uses by humans, as well as marine debris and accumulations from harmful algal blooms, also pose a significant threat. In the longer term, the cays ecosystems and fauna are

Fig. 10 The challenge of managing for people and biodiversity, as shown through recreational boat use of Cayo de Barca, Jobos Bay National Estuarine Research Reserve, Puerto Rico (Murry et al., 2020). Photo credit: E. Rodríguez.

expected to show high exposure and sensitivity with limited adaptive capacity, depending on the type of island, to the impacts of climate change. This can be countered by using a strategic adaptive approach to utilize projections of future conditions for decision making.

As described by [Harrington et al. \(2020a\)](#), the Hawaiian archipelago is the most isolated landmass in the world, approximately 3846 km from California and 6196 km from Japan. These islands range from small atolls in the northwest of the archipelago, to high volcanic islands in the southeast, and contain a range of ecosystems due to variations in elevation, topography, substrate,

Fig. 11 Mean annual air temperature and precipitation across the main Hawaiian Islands (Harrington et al., 2020a).

hydrology, wind, and precipitation patterns (e.g., Fig. 11). Hawaiian coastal ecosystems were highly intact native coastal communities prior to human contact. These became heavily impacted post human contact and now require protection and restoration by local conservation and community groups for continued survival of native coastal species (Kim et al., 2020). Two coastal ecosystem sub-types occur in the archipelago and are defined by moisture regime: coastal dry and coastal wet-mesic sub-types. Coastal ecosystems were historically more resilient to stochastic events because they had more continuous populations of native flora with a higher faunal diversity. Currently, coastal ecosystems are in decline due to factors such as conversion pressure from expanding development and agriculture and the introduction of invasive species. The future of these communities will be based on the effectiveness of collaborative management of these coastal ecosystems.

Harrington et al. (2020b), describe the 15 islands (the largest of which is Guam) and various small islets of the Mariana Archipelago, which is famous for the Marianas Trench, the deepest location known on earth. The vast majority of the archipelago's land area is concentrated in the larger, southern main islands of Saipan, Tinian, Rota, and Guam. Plentovich et al. (2020) describe the status, stressors, and future viability of coastal strand and mangrove swamps of the Marianas. Of particular interest is their descriptions of the current conditions as they relate to future scenarios based on items of social interest, conservation values, laws and biosecurity, and long-term planning (Fig. 12).

The biodiversity of the Galapagos Islands (Elias, 2020) has a rich and storied history in ecology, famous for the basis of thought that Charles Darwin (Fig. 13) developed from his visit there in his youth. Current conservation efforts in the Galapagos relate strongly to ecotourism, and biosecurity measures seek to prevent the spread of terrestrial and marine invasive species.

Yuni and Yuda (2020) discuss the remarkable degree of endemism in Wallacea, a region that consists of three distinct island groups, Sulawesi, Lesser Sunda, and Moluccas (Fig. 14). They describe the geologically young islands of Sulawesi, with flora and fauna that evolved independently and high avian biodiversity of the Moluccas region, with 83 endemic species out of the nearly 600 species known. They also describe the dramatic Krakatoa Island, whose violent 1883 eruption, and subsequent eruptions has provided opportunities for long term ecological research on tropical island biogeography and succession.

Ito et al. (2020) describe another topic that transcends many islands, atolls, and archipelagos, a transported landscape. Ancestors of the Marshall Islands brought domestic plants and animals such as pigs, dogs, chickens, taro, breadfruit, and bananas from their original lands, and this became known as the portmanteau biota. In Majuro, the transported landscape has continued throughout the 2000 year human history. Parts of the Marshall Islands, such as Bikini Atoll and Eniwetok Atoll, have experienced adverse anthropological impacts such as nuclear testing conducted after World War II (resulting in food chain effects that led to iodine deficiency in humans, as in Fig. 15), and heavy metal contamination from industrial waste.

Not all islands are marine, however, and this volume has one unique article on a collaborative landscape conservation effort to conserve the Madrean Sky Islands (Sittig et al., 2020). In the Madrean Sky Islands (Fig. 16), deserts meet mountains in a patchwork

Fig. 12 Coastal development along the western coast of Saipan near the town of Garapan (Plentovich et al., 2020). Photo credit: R. Walker.

of multiple biomes including desert, scrub, grassland, woodland, and forest. The Sky Islands of the United States and Mexico contain a unique ecology of rarity and endemism, whose geography spans international borders, whose social values are different than the surrounding areas, and where stressors and threats to the ecological health islands create many challenges. The article provides an example of work by multiple agencies, organizations, and individuals to overcome physical and social boundaries

Fig. 15 Urinary iodine excretion in the Majuro and Likiep Atolls (Ito et al., 2020).

Fig. 16 The mountain ranges of the Madrean Sky Island ecoregion of the United States and Mexico (Sittig et al., 2020). Photo credit: Sky Island Alliance.

Fig. 17 By kayak, in 2019, Tongass National Forest—Sitka Ranger District staff and volunteers removed over 600 pounds of trash and recyclables from 12 beaches in the West Chichagof-Yakobi Wilderness Area. The haul included many Japanese plastic bottles which may have arrived in the wake of the 2011 Honshu tsunami. Photo credit: Voices of the Wilderness Artist in Residence, Cecil Howell.

to conserve natural resources. It describes challenges, lessons learned, and available tools and resources to the Madrean Landscape Conservation Design in order to inform and provide connections to conservation work elsewhere.

It became quickly apparent that although the authors would cover a great deal in this section, we could not cover everything. For example, although invasive species and biosecurity were discussed among many papers, no single treatise on invasive species and eradication is found here. Another topic that is similarly addressed among many papers is one of coastal pollution. As part of a recent monitoring trip to a Wilderness Area near where I live, volunteers picked up and packed into kayaks 580 pounds of non-recyclable plastic and six contractor bags of recyclable plastic and aluminum (Fig. 17). They cleaned a short stretch of shoreline including 12 beaches. Trash issues on islands, atolls, archipelagos, as well as in freshwater and across oceans, are an ever growing concern worthy of mention here.

Summary

The papers in the Islands and Atolls section take a new look at the distribution of global islands, revisit island biogeography, describe some geographic areas in great depth, and discuss complex histories, the potential effects of sea level rise and storm surges, and uncertain futures. The papers here provide an overview of complex and rich biogeography of the *Islands and Atolls of the World*.

Abstract

A new map of global islands at a high spatial resolution (30 m) has been produced from a semi-automated interpretation of 2014 satellite imagery. The data are available in the public domain. The islands were classified by size into continental mainlands (5), big islands $> 1 \text{ km}^2$ (21,818), and small islands $\leq 1 \text{ km}^2$ (318,868). The new high-resolution islands data are intended to support coastal ecosystem mapping efforts and assessments of threatened island biodiversity, among other applications. This chapter summarizes the global island mapping approach and results.

Islands vary greatly in shape, size, and composition, from small, virtually lifeless rocky outcrops to continental-scale landmasses teeming with life. If an island is simply defined as an area of land surrounded by water on all sides, then all the landmasses on Earth are considered islands, regardless of size. Due to their geographic isolation, islands often have high levels of endemism ([Whittaker and Fernández-Palacios, 2007](#)) and are often considered as important candidates for biodiversity conservation efforts, especially since extinctions and other biodiversity losses on islands are disproportionately more rapid ([Spatz et al., 2017](#)). It is therefore important to understand exactly how many islands there are on Earth, where they are located, how big they are, what biodiversity they contain, and what condition their ecosystems are in.

Many attempts have been made throughout history to map and characterize Earth's islands, but a definitive characterization is still lacking. With the help of increasingly high-resolution satellite imagery and geographic information system (GIS) processing, our understanding of global island geography has improved. A new map of global islands ([Sayre et al., 2018, 2019](#)) was recently created from 30 m spatial resolution, 2014 composite Landsat satellite imagery. The islands data were produced by the U.S. Geological Survey (USGS) and Esri under a commission from the intergovernmental Group on Earth Observations (GEO) to produce standardized, global ecological coastal units.

The GEO is a consortium of over 100 nations, which seeks to leverage the use of Earth observations to help solve societal challenges ([GEO, 2005](#)). One of GEO's initiatives is the development of a standardized, robust, and practical map of global ecosystems for terrestrial, freshwater, and coastal/marine environments ([Sayre et al., 2007](#)). The USGS is the designated federal agency implementing the GEO initiatives in a public/private partnership with Esri. Terrestrial ecosystem distributions were delineated using a structure-based mapping approach, where ecosystems were produced from the integration of data on climate regime, landforms, substrate, and land cover ([Sayre et al., 2014](#)). Subsequently, oceanic marine ecosystems were systematically mapped into volumetric regions based on ocean physical and chemical characteristics ([Sayre et al., 2017](#)). The resolution of the marine ecosystem mapping effort was sufficient for the open ocean but did not accurately characterize the coastal zone and its associated ecosystems. The USGS/Esri team therefore decided to develop an additional map for global coastal ecosystems.

For coastal ecosystem mapping, globally-consistent, high-resolution global shoreline vector data were needed. Annual composite 2014 Landsat satellite imagery was classified into two feature classes, land and ocean, using a semi-automated approach. An analyst manually identified thousands of training points from all of the planet's coastlines by visual inspection. These points were then used in a computer-based classification to delineate a new global shoreline vector. Antarctica was not included in the analysis, in part due to the difficulty in separating ice features from land features. During the automated classification step, a minimum mapping unit of four contiguous 30 m Landsat pixels was used, so islands smaller than the 3600 m^2 threshold were not identified and were therefore not included in the new global islands resource. A full description of the image-based island extraction methodology can be found in [Sayre et al. \(2018\)](#).

The resulting dataset contains 340,691 polygons, five of which represent the five continental mainlands of North America, South America, Africa, Eurasia, and Australia. North and South America were algorithmically separated by the Panama Canal, and Eurasia and Africa were similarly separated by the Suez Canal. For the remaining polygons, those larger than 1 km^2 are attributed as "big islands" and those smaller than 1 km^2 are attributed as "small islands." The new map of global islands is depicted in [Fig. 1](#), and the results from the size class analysis are presented in [Table 1](#).

Since this new set of island features was derived from primary interpretation of satellite imagery, the polygons initially lacked attribute information. Island name was considered the priority attribute field for development, and a three-phase island naming

Fig. 1 Map of global islands. Continental mainlands are depicted in brown, islands bigger than 1 km² (big islands) are depicted in green, and islands smaller than 1 km² (small islands) are depicted in red. Note that the small islands, normally not visible at this map scale, are depicted here with exaggerated symbology (heavier outlines) to permit visualization.

Table 1 Number, total collective area, and coastline length for islands in three size classes.

Landmass type	Number of polygons	Area (km ²)	Length of coastline (km)
Continental mainlands	5	125,129,046	813,467
Islands > 1 km ²	21,818	9,938,964	1,304,762
Islands ≤ 1 km ²	318,868	20,589	321,774

process was initiated. The first phase was to manually name the 1000 largest islands in the United Nations Environment Programme (UNEP) Islands Directory (Dahl, 1991). Esri's WorldImage Basemap®, Open Street Map®, and Google Maps® were used as sources of information to manually identify names for these 1000 largest islands. While naming these islands, an additional ~2000 islands were opportunistically named and labeled because it was expedient to do so while zoomed in on a particular map extent with clusters of islands. At the end of this phase, 3156 big islands and 686 small islands were named. This process was considered accurate but very time-intensive.

For more efficient name attribution, an automated approach was used for phase 2. The island polygons were intersected with the GeoNames data, which are freely available point-based data containing geographical place-names for a variety of features including islands (<https://www.geonames.org/>). The phase 2 effort to match island polygon centroids with GeoNames data points resulted in the naming of an additional 5340 big islands and 12,253 small islands. While the automated naming approach was successful in assigning thousands of island names, over 60% of the big island polygons and 99% of the small island polygons still lacked name attributes at the end of phase 2.

During phase 3, the naming of small islands was discontinued due to the enormity of the effort, which would have required manually identifying names for the remaining ~305,000 small islands. For the remaining ~13,000 big islands, a return to the manual naming approach was implemented, again using Esri's WorldImage Basemap®, Open Street Map®, and Google Maps® as the source information for island names.

While developing name attributes, several conventions were used. First, only the proper noun, in English, was considered, and the descriptor "island" was not used. For example, the polygon representing Hilton Head Island in South Carolina, USA, was given a name attribute of "Hilton Head," not "Hilton Head Island." At times, this rule was sometimes difficult to enforce especially with non-English names, and exceptions to the convention were made. For example, for Isla Saona, a Dominican Republic island, the

English equivalent would be Saona Island, which would then be attributed as Saona. However, the island is universally referred to as Isla Saona, by English speakers and non-English speakers, so the name was therefore attributed as Isla Saona. For the same reason, the name Isle of Man was retained as is.

Only the 26 letters of the English alphabet (ISO basic Latin alphabet) were used. Diacritical marks, like accents, cedillas, tildes, and umlauts, were eliminated such that all names have been reduced to the simplest possible English language formulation. The attribute "UNNAMED" was given to island polygons when a name was lacking or not available in English, but it is recognized that there are very few islands on the planet that are, in reality, unnamed. Many fluvial islands, difficult to identify in the first place due to frequent change in their size, shape, and location, were also attributed as UNNAMED.

For easy access to and visualization of the integrated global coastal data, a web-based query and exploration tool called the Global Islands Explorer (<https://rmgsc.cr.usgs.gov/gie>) was developed. This tool allows anyone with access to the internet to zoom in on any island of interest and inspect its shoreline polygon on top of a number of backdrops (as in Fig. 2). The full set of polygons in the global island dataset is also available for download at the Global Islands Explorer website.

Future work and new collaborations are in development to improve the Global Islands data. Existing linework is being inspected for accuracy and needed improvement, and the potential for additional attribution is being evaluated using data from the UNEP World Conservation Monitoring Centre (WCMC) as well as a set of ~3000 islands that have been extensively characterized through invasive species and biodiversity conservation work (Spatz et al., 2017). The WCMC resource includes additional island polygons for islands smaller than the 3600 m² minimum mapping unit that are being added to the Global Islands resource.

In conclusion, a new set of some 340,000 global islands has been objectively and transparently developed and is freely accessible in the public domain as GIS polygon features. The resource facilitates an understanding of global island geography. Work is underway to improve the resource in terms of adding additional islands, improving linework, and enriching attribution.

Any use of trade, firm, or product names is for descriptive purposes only and does not imply endorsement by the U.S. Government.

Fig. 2 Island polygons for St. Thomas, U.S. Virgin Islands, and surrounding islets. Island polygons for islands with an area $> 1 \text{ km}^2$ are shown with green outlines, and islands with an area $\leq 1 \text{ km}^2$ are shown with red/orange coastlines. The island polygons are shown on top of satellite imagery, where the fit of the shoreline linework to the shoreline discernible in the imagery can be visually inspected

Abstract

For centuries, naturalists have been intrigued by islands. Patterns in island biodiversity are the basis for fundamental theories in ecology such as island biogeography theory (IBT). Under this theory, the biodiversity of islands is a function of three processes: immigration, evolution and extinction. Immigration from source pools and subsequent evolution adds biodiversity to islands. Evolution allows immigrants to adapt to island habitats and evolve into new species. In contrast, extinction subtracts species. In a natural context, these three processes are a function of island area and isolation. Larger islands have more immigration, more evolution, and less extinction and thus more biodiversity than smaller islands. Isolated islands have more evolution, but less immigration and higher extinction resulting in lower biodiversity than proximate islands. Understanding how geography influences these three processes is the focus of IBT. Here, we review the history of island biogeographic study, discuss main themes of IBT, and place IBT in the context of the Anthropocene where humans are greatly impacting island immigration, evolution and extinction.

What Is Island Biogeography?

Biogeography is the study of the processes that determine the spatial and temporal distributions of organisms and their attributes across the earth (Lomolino et al., 2017). Biogeography focuses on understanding the geological, environmental, and historic factors that determine where biodiversity is and how it is different among regions. Geographic regions are defined by physical characteristics such as mountains, climate, or water. The boundaries among regions are not always well defined and can be broad gradients that are a mix of physical characteristics between neighboring regions. However, the boundaries of islands are well delineated because they are surrounded by water making them one of the most distinct type of region.

Island biogeography is the geographic study of the terrestrial, aquatic, and marine biodiversity of islands. Island biogeography is in part determined by island type. There are two natural types of islands: “continental” and “oceanic.” Continental islands reside on the continental shelf and were once connected to the continental mainland. They are often proximate to the continental mainland and as a result have many organismal groups in common with the mainland. Continental islands can be large in area such as Madagascar and Cuba. In contrast, oceanic islands are small, reside on the oceanic crust, and are mostly volcanic in origin. Atoll islands are coral reefs that have grown on top of submerged oceanic islands. Oceanic islands are often found distant from the mainland, and as a result, they are naturally isolated from the mainland and have only those species that are able to disperse long distances overwater (Helmus and Behm, 2018).

Today, island biogeography must be revisited to account for a third type of island: “artificial.” Artificial islands are made by draining water from seafloors or from pilling dredged sediment and sand onto seafloors and submerged coral reefs, which can have substantial impacts to marine species (e.g., de Groot, 1979). Artificial islands can vary considerably in their isolation from the mainland, but both continental and oceanic islands tend to be larger than artificial islands. Little is known about the biodiversity of artificial islands, but most of the species are likely introduced by humans.

History of Island Biogeography

For centuries, naturalists have studied island biogeography (Lomolino et al., 2004). Carl Linnaeus (1707–78) speculated that oceans once covered the earth except for a tall mountain range that formed an island close to the equator where all species on earth were created to match different altitudinal environments on the island. As water receded, the immutable species spread to fill earth’s different environments. In opposition to Linnaeus’s speculation, his contemporary Georges-Louis Leclerc Comte de Buffon (1707–88) amassed volumes of information on species distributions and found that regions with similar climate and environments

do not have the same plants and animals—as they would in Linnaeus’s argument—instead they have distinct plants and animals indicating that species change. This concept became known as Buffon’s law and was reaffirmed by other naturalists such as Joseph Banks (1743–1820) and Johann Reinhold Forster (1729–98) who circumnavigated the globe with James Cook cataloging geographically distinct species while comparing islands and the mainland. Forster was one of the first to describe positive species-area and negative species-isolation relationships; that is, the tendency of the number of species to increase as island area increases and decrease as island isolation from the mainland increases (Forster, 1778). The documentation of all these patterns led to the realization that life evolves in response to geographic and environmental factors.

Charles Darwin (1809–82) and Alfred Russel Wallace (1823–1913) independently conceived the theory of evolution by natural selection by observing island biodiversity. As evidence for evolution, Darwin argued that island species were more taxonomically similar to species on the closest continent even if the environment of that continent was different from the island. He wrote: “. . . there is a considerable degree of resemblance in the volcanic nature of the soil, in climate, height, and size of the islands, between the Galapagos and Cape de Verde Archipelago: but what an entire and absolute difference in their inhabitants! The inhabitants of the Cape de Verde Islands are related to those of Africa, like those of the Galapagos to America. I believe this grand fact can receive no sort of explanation on the ordinary view of independent creation” (Darwin, 1859). Alfred Russel Wallace independently devised the theory of evolution based in part on his work in Malay Archipelago. He identified a taxonomic divide located in the Malay Archipelago that delineates species derived from Southeast Asia vs. Australia due to past land connections when sea level was lower (Wallace, 1860). His book *Island Life* (Wallace, 1880) was the first comprehensive volume on island biogeography. It included a worldwide survey of island species and distinguished the two classes of islands, oceanic and continental, and how they differ in isolation. He argued that because oceanic islands are isolated from the mainland, they are colonized only infrequently by species that can immigrate over water. In contrast, continental islands are less isolated because they were once connected to the mainland and as a result have more species that are related to those of the mainland including species that did not need to colonize over water (e.g., large mammals).

Immigration, Evolution, Extinction

These early naturalists identified three fundamental processes that determine island biogeography: immigration, evolution and extinction (Lomolino et al., 2009). Species immigrate to islands by dispersing, often overwater, with some species groups more likely to disperse than other species groups (e.g., birds vs. frogs). Because the species that have immigrated to islands are often isolated from their source populations, island species evolve both by adapting to island life and randomly diverging from their source population (genetic bottleneck and drift). Finally, species naturally go extinct from islands as geography and the environment change.

Nearly a century after the early naturalists’ fundamental work on island biogeography and evolution, Robert H. MacArthur and Edward O. Wilson formulated a theory of island biogeography (IBT) based on immigration, evolution, and extinction and how they are determined by island area and isolation (MacArthur and Wilson, 1963; MacArthur and Wilson, 1967; Wilson, 1969). According to the theory, the biodiversity on an island is determined by immigration to the island followed by evolutionary adaptation to the island and subsequent extinction of that biodiversity. For simplicity, the measure of biodiversity often used is species richness (i.e., number of species). Immigration increases island species richness, and evolution, if it leads to vicariant speciation (i.e., the splitting of one species into two species), also increases species richness. Extinction of species from the island reduces species richness. Under IBT, the rates of these processes are determined by island area and isolation (Fig. 1). While other geographic and environmental factors such as island elevation, latitude, age, and habitat heterogeneity certainly influence island biodiversity; area and isolation are

Fig. 1 Island biodiversity is determined by three fundamental biogeographic processes: immigration, evolution, and extinction. These three processes vary with island area and isolation from source pools of immigrants. Arrows depict relationship direction.

still considered the most important explanatory factors (Whitehead and Jones, 1969; Heaney, 2007; Whittaker et al., 2008; Warren et al., 2015).

Island Area and Isolation

Island area is typically defined as the amount of two-dimensional terrestrial surface area, and it affects all three biogeographic processes. Larger islands have more immigration because larger islands are a larger target for dispersing individuals to land. Larger islands have more resources, habitats and space for populations to evolve and speciate. Similarly, extinction is lower on larger islands because there are more resources and space for populations to grow large and be less prone to stochastic extinction events (Fig. 1).

Island isolation is defined by an island's distance from potential sources of colonists. Common metrics of isolation range from simple metrics of just the distance to the nearest continent, or more complex metrics that include distances to larger islands, island groups, or prevailing currents (Weigelt and Kreft, 2013). Like area, island isolation affects all three biogeographic rates (Fig. 1). The primary influence of isolation is on immigration rates whereby isolated islands tend to have lower immigration than proximate islands. Evolution is also higher on more isolated islands because colonists are isolated from gene flow from the source population and thus evolve independently (Heaney, 2000; Pinheiro et al., 2017). Extinction is also higher on isolated islands because populations on isolated islands cannot be rescued from extinction by immigration from source populations (Brown and Kordic-Brown, 1977).

According to IBT, the maximum number of species that an island can contain is called its saturation point. This point is determined by island area and the number of species in the species pool; that is, the total number of species that could potentially colonize the islands. Due to speciation and extinction occurring in source areas, island species pools are not static. In the extreme case, all species from the pool can immigrate to and establish on an island, but this is never the case in nature. The saturation points of islands are determined by island area with larger islands having higher saturation points than smaller islands because larger islands have higher immigration, higher evolution that leads to vicariant speciation, and lower extinction.

Island isolation determines how close an island of a given size is to its saturation because isolated islands have lower immigration and higher extinction. When the effects of area and isolation on the three rates are in balance, then the island is said to have reached its equilibrium point. In the Anthropocene, humans are modifying immigration, evolution and extinction and shifting island equilibrium points.

Immigration Is Higher Due to Human Introductions

The rate at which nonnative, exotic (i.e., alien) species are being introduced to islands is increasing. The richness of birds, mammals, lizards, plants and invertebrates have all greatly increased on islands (Sax et al., 2002; Dawson et al., 2017). Exotic species have been introduced both intentionally and unintentionally by humans to islands for centuries, but today due to global trade, exotic immigration rate is currently the highest ever seen, and the species that are immigrating are coming from long distances.

By introducing exotic species at higher rates, humans are essentially decreasing island isolation (Helmus et al., 2014; Moser et al., 2018). For example, while the richness of native anole lizards in the Caribbean is lower on isolated islands, the richness of exotic anoles is higher on isolated islands. This is expected according to IBT because isolated islands should be farther from their saturation point and can thus gain more species than less-isolated islands closer to their saturation points when immigration rate increases. Human introduction of anole species has essentially increased anole immigration rate. Today, instead of geographic isolation limiting exotic immigration, it is economic isolation. Economic isolation is measured as the degree that islands are connected to human trade such as shipping traffic. In the Caribbean, islands that are the least connected by shipping trade have the lowest immigration rates of exotic anole species (Helmus et al., 2014).

By introducing exotic species from long distances, humans have expanded the potential species pool of immigrants (Seebens et al., 2018). In the past, species mostly immigrated to islands from the nearest mainland or from nearby islands. For example, the Caribbean has many native gecko lizard species found across all the islands. Like most Caribbean reptiles, most native gecko species of the Caribbean are derived from South America (Hedges, 2006). Today, the Caribbean has been colonized by several exotic gecko species, many from tropical Asia, Africa and the Mediterranean. The long-distance immigration of the exotic geckos began during European colonialism that moved many people and products among hemispheres essentially expanding the species pool of geckos for Caribbean islands (Perella and Behm *in review*).

Evolution in Response to Human Impacts

Human impacts are a strong selective force acting on native island biodiversity. Humans alter species interactions by introducing species and altering habitats by removing native vegetation, building structures and transforming landscapes. If native species can evolve in response to these impacts, then they are less prone to extinction. However, island species are considered to have less

adaptive genetic variation than mainland species thus reducing their potential for evolution (Frankham, 1997). Regardless, native species on islands have been shown to adapt to human impacts.

Introduced species are a major force that drives evolution on islands (Mooney and Cleland, 2001; Strauss et al., 2006). For example, the mosquito *Culex quinquefasciatus* is a vector for avian malaria (*Plasmodium relictum*). Both were introduced to the Hawaiian Islands in the 1800s (Atkinson and LaPointe, 2009). The introduction of this disease greatly decreased native bird populations particularly Hawaiian honeycreepers, but this decrease acted as a selective force driving resistance to the disease in amakihi honeycreepers (Foster et al., 2007). Other examples of evolution of native island species in response to introduced species include native island plants that have evolved resistance to introduced herbivores (Vourc'h et al., 2001) and lizards that evolved different behavior and morphology in response to the introduction of lizard competitors and predators (Losos et al., 2006; Stuart et al., 2014). Introduced species also evolve following introductions to islands. For example, introduced plants have evolved reduced dispersal ability on islands similar to the reduced dispersal ability seen in native island plants (Cody and Overton, 1996) and introduced plants often adapt to novel island habitats (e.g., Dlugosch and Parker, 2008). Similarly, introduced lizards adapt their morphology in response to the novel habitats provided by islands (Herrel et al., 2008).

While introduced species can adapt to island habitats, resident island species also adapt to human alterations to their habitat. Urbanization is a strong selective force on islands (Johnson and Munshi-South, 2017). For example, *Anolis cristatellus* lizards on Puerto Rico naturally perch and climb on trees, but in developed areas of the island, lizard phenotypes have shifted to be better adapted to perch on human structures such as tiled walls (Winchell et al., 2018). *Aedes albopictus* mosquito populations in urban areas on Réunion Island are genetically differentiated from forested areas; urban areas provide human hosts and larval development sites that are different from unpopulated and undeveloped forested areas (Delatte et al., 2013).

We hypothesize that evolution of native island species in response to human impacts should be higher on larger islands and lower on isolated islands. The rationale for this hypothesis is on how area and isolation naturally affect island biodiversity. Larger islands have species with larger population sizes, thus species on large islands on average should have more phenotypic and genetic variation on which evolution can act and have more refuge from human impacts that provide time for adaptations. In contrast, smaller islands have smaller populations with less variability and less refugia from human impacts especially if those impacts are island wide. Isolated islands have low native biodiversity derived from few immigration events that can cause genetic bottlenecks that reduce adaptive genetic variation. Further, the biodiversity on isolated islands has often evolved in the absence of intense predation, herbivory and disease. Antipredator and other defenses are energetically costly and are lost from island populations released from such antagonistic interactions; a process termed the evolution of island-tameness. As a result, the ability to withstand and adapt to human impacts such as introduced predators before going extinct should be lowest on isolated islands. While the influence of island area and isolation on evolution in the Anthropocene has not been well studied, one example exists. Populations of Aegean wall lizards (*Podarcis erhardii*) across the Greek Cyclades are more tame on small and isolated islands that do not have introduced predators, while those with predators are less tame (Brock et al., 2015).

Human-Caused Extinction Is Higher on Islands

Islands make up only about 5% of the total land area on earth, yet over 60% of all known human-caused extinctions come from islands (Tershy et al., 2015). Island species are more threatened with extinction than mainland species, and much of this extinction is due to invasive predators such as cats and rats (Blackburn et al., 2004; Medina et al., 2011; Spatz et al., 2017). Island extinctions have been occurring throughout human history. For example, one of the best-known extinctions is the dodo bird once found only on the island of Mauritius. This bird was large and unafraid of humans and did not have natural defenses to predators. As a result, when Europeans colonized the island, they drove it to extinction through hunting and by introducing mammals such as cats and rats that fed on dodo eggs and chicks (Fuller, 2004). Bird extinctions on islands have been high. Polynesian colonization of the Hawaiian Islands precipitated the extinctions of several bird species due to introduced mammals, hunting, and deforestation, but then European colonization brought a second round of bird extinctions (Boyer, 2008). Similarly, extinction on Madagascar had been in two phases. First, prehistoric human colonization coincided with the extinction of giant lemurs and other megafauna, and today, resource extraction and illegal deforestation and hunting are causing Madagascar to have one of the highest extinction rates on earth (Burney, 2004; Perez et al., 2005; Jones et al., 2019).

The effect of island isolation on extinction is clear. Isolated islands have higher Anthropocene extinction rates than less isolated islands. This is thought to be due to genetic bottlenecks, island tameness, and increased island endemism that increases extinction susceptibility on isolated islands. In contrast, the effect of area on extinction rate is less clear. Smaller islands naturally are theorized to have higher extinction rates, and many small islands have seen high extinction rates. However, because larger islands have more endemic species and more people, larger islands also can have very high extinction rates. This unclear effect of area on extinction may be due to when extinction rate is determined, in the past or in the present. For example, birds that have already gone extinct disproportionately come from small islands, but birds that are threatened with extinction currently are more likely to be found on larger islands (Blackburn et al., 2004).

Island Biogeography Revisited for the Anthropocene

Like past biogeographers who built upon the research of early naturalists, today's researchers of island biogeography build upon vast amounts of published data. Many of the studies on island biogeography in the Anthropocene aggregate large data sets (e.g., Blackburn et al., 2004; Helmus et al., 2014; Moser et al., 2018; Silva-Rocha et al., 2019). These studies have identified three major trends that make it necessary to revisit island biogeography. First, island equilibrium points are increasing in the Anthropocene. While extinctions on islands are high, the number of introduced species on average is much greater than the number of extinct native species. Second, island evolutionary history is being obscured in the Anthropocene. Area and isolation created measurable evolutionary signatures on island biota, but native species are adapting to human impacts and introduced species are from new evolutionarily distinct species pools. Finally, economic geography has become more important than physical geography in determining island biogeography. The economic isolation of islands now determines immigration rates more than geographic isolation, while the level of development and habitat loss for agriculture and resource extraction that an island undergoes determines extinction rates. We do not know exactly what island biodiversity will look like in the Anthropocene, but what is clear is that it will differ from the natural biogeography of the past.

Abstract

Marine shallow-water habitats include reefs, sand beaches, kelp forests, estuaries, and others, which have a high biological and economic importance. The study of island biogeography has uncovered the processes shaping species distribution patterns and have recently expanded to encompass the marine realm. In this article we provide an overview about marine shallow-water island biogeography. We explore the taxonomic and functional marine island biogeography, considering islands area, isolation, and geological age, as well as scale and taxon-dependency. We then discuss endemism patterns and speciation in remote marine systems and conclude with a discussion about methods of studying island biogeography in such habitats.

Introduction

Marine shallow-water habitats are normally considered as those within the neritic zone (littoral and sublittoral), typically extending to the edge of the shelf. In continental shelves this can reach as down as 200 m depth, although the shelf-break in islands generally occurs on shallower depths (Lalli and Parsons, 1997). These shallow-water habitats include reefs (rocky, biogenic or artificial), sand beaches, kelp forests, and estuaries (including marshes and mangroves; Fig. 1). The latter, although brackish, is closely associated with the sea and can be considered the most productive of the marine systems (Hemingson and Bellwood, 2018).

These marine shallow-water habitats have high biological and economic importance. For instance, marine shallow-water habitats are occupied or visited by 34 of the 35 extant animal phyla, and half of them are exclusively marine (Carr et al., 2003). Notwithstanding, they provide services as coastline protection, food production, nitrogen fixation, carbon dioxide sink, within others (Moberg and Folke, 1999; Holmlund and Hammer, 1999). But, besides its importance, the comprehension of most of these systems remains poor when compared to terrestrial and freshwater systems (Field et al., 2008).

Island biogeography, as a science that studies biodiversity distribution through the globe, has advanced our knowledge about the processes shaping species distribution patterns, and how physical and biological aspects of islands and species interfere on such patterns. The theories of island biogeography were initially built upon terrestrial island systems and have been extended to marine systems more recently (Hachich et al., 2015; Pinheiro et al., 2017; Ávila et al., 2019).

In this article we explore marine island biogeography through the perspective of shallow-water organisms. Our overall goal was to provide an overview of processes and patterns related to marine shallow-water island biogeography, considering taxonomic and functional biodiversity, as well as scale and taxon-dependency. We start by briefly presenting the most prominent island biogeography theories. This sets a theoretical background for the discussion of differences between terrestrial and marine island biogeography. We then present the state of art for taxonomic marine island biogeography, considering species-area, species-isolation and species-age patterns, as well as the applicability of more complex models on explaining marine shallow-water species richness distribution. The next section includes the discussion about marine island biogeography related to the functional component of diversity. We then proceed giving more emphasis to speciation and endemism patterns in marine systems, and finish with a brief discussion about methods of studying island biogeography in such habitats. Although reefs are by

far the most well studied marine shallow-water habitats, as are reef fish, gastropod and seaweed the most well studied marine shallow-water groups, examples on other shallow-water habitats and taxa were brought to light whenever as possible.

Classical Theories of Island Biogeography: Predicted Patterns

The Theory of Island Biogeography (IBT) predicts a variation of species richness with island area and isolation ([MacArthur and Wilson, 1967](#)). According to the IBT, the species–area relationship (SAR) is due to larger habitat heterogeneity, that results on lower extinction rates and therefore, higher species richness maintenance. At the same time, such richness is expected to decrease as a function of island isolation, due to reduced immigration rates.

Further studies of island biogeography also pointed for an increase in species richness with island geological age due to longer times for species accumulation either by arrival of new immigrants or arise of a new species by speciation ([Rosenzweig, 1995](#)). The General Dynamic Theory of Oceanic Island Biogeography (GDM; [Whittaker et al., 2008](#)) also included island age as an important factor for predicting islands species richness, combined with island area. The explanation for the GDM also relies into the interaction between immigration, speciation and extinction rates. According to the GDM, species richness would increase linearly with island area, but would vary as a unimodal function of island age, due to the variation of habitat heterogeneity in the life cycle of an oceanic island. Such islands, which are mainly volcanic, tend to increase in area and height in their youth, due initially to volcanic activity and latter to erosion (that also increases habitat heterogeneity). An advanced stage of erosion leads to loss of habitats—increasing extinction rates—and, in older stages, the disappearance of the island, turning into an atoll or seamount, sinking into the sea.

Besides the influence of island area, age and isolation in species richness, it is also expected for those environmental variables to affect the level of endemism in islands. In the terrestrial realm, bigger islands are expected to show increased numbers of endemics, given the possibility of diversification driven by sympatric and ecological speciation—a process known as adaptive radiation. Older islands are also expected to show increased levels of endemism, due to longer times for cladogenesis. Notwithstanding, isolated islands shall exhibit increased percentage of endemic species as well, due to reduced gene flow.

The processes that influence biodiversity distributions on terrestrial and marine realms—i.e. immigration, speciation and extinction—although the same, interact differently and vary differently with such island physical features (area, isolation and age), leading to differences on island biogeography patterns.

Island Biogeography Patterns and Process of Marine Shallow-Water Organisms

Understanding island biogeography patterns for marine shallow-water organisms is key for the conservation of marine systems. For example, the richness patterns of reef fishes, corals, marine snails and lobsters are concordant across the globe and such richness is mainly concentrated in islands, with a predominance of their centers of endemism in the most isolated ones ([Roberts et al., 2002](#); [Tittensor et al., 2010](#); [Fig. 2](#)).

Fig. 2 Distribution of different marine shallow-water taxa across the globe. For seagrasses and mangroves only plant species were considered. Figure from Tittensor, D. P., Mora, C., Jetz, W., et al. (2010). Global patterns and predictors of marine biodiversity across taxa. *Nature* **466**, 1098–1103.

Yet, although the term biodiversity was originally related to the number of biological species units solely (Wilson and Peter, 1988), on a broader concept, biodiversity could embrace any variety of life. Moreover, the study of the diversity of species ecological traits and evolutionary history contributes to elucidate the processes shaping the distribution of the marine shallow-water biota in islands (Cavender-Bares et al., 2009). For this reason, we discuss herein the island biogeography patterns relying not only on taxonomic metrics of biodiversity but also on a functional approach.

Taxonomic Approach

The taxonomic approach for community ecology is based on the species as the lower measurable unit of biodiversity. The most classical island biogeography theories, briefly presented above, were developed upon this concept.

Species–area relationship

With regards to the most accepted biogeography pattern—the species–area relationship (SAR)—an increase of species richness with area is observed as a multiscale general pattern in both terrestrial and marine systems. For shallow-water marine organisms, the SAR was already detected with multiple taxa, on multiple geographical regions and over multiple spatial scales. This fact strengthens the statement as the SAR being “one of community ecology’s few genuine laws” (Schoener, 1976). Although few variations were shown, the power-model seems to be the best to explain SAR in both marine and terrestrial systems (Hachich et al., 2015; Triantis et al., 2012).

On a global scale, evidences of SAR were observed for reef fish (Parravicini et al., 2013; Pérez-Ruzafa et al., 2005), molluscs and echinoderms (Pérez-Ruzafa et al., 2005). On an oceanic scale, an increase of species richness with area was evident in the Atlantic Ocean for reef fishes, gastropods, seaweeds (Fig. 3; Hachich et al., 2015, 2016) and echinoderms (Ávila et al., 2018), and for reef fishes and corals in the Indo-Pacific Ocean (Bellwood and Hughes, 2001).

At the scale of a biogeographic region, the SAR was evident for reef fishes in the Caribbean (Sandin et al., 2008), and for sponges in the Eastern Atlantic (Xavier and Van Soest, 2012). The variation in seaweeds species richness between islands in the same archipelago, in the Lusitanian Macaronesia region, that comprises Azores, Madeira, the Salvage and Canary Islands, also varied in function of islands area (Tuya and Haroun, 2009), and the patterns found were consistent when considering red, green and brown algae separately or the three groups together. At smaller scales, the SAR was also evident in marine systems; the richness of decapod crustaceans associated with coral in the Gulf of Panama increases in function of coral heads sizes (Abele and Patton, 1976), and the richness of sessile and mobile marine invertebrates increased with boulders sizes in New South Wales (McGuinness, 1984).

The main explanation for SAR is equivalent for terrestrial and marine systems: bigger islands are expected to hold greater habitat variability and maintain larger populations, experiencing lower extinction rates and sustaining higher species richness. The target effect explanation, in which larger islands are more prone to be reached by chance by a propagule, has also been evoked for marine island biogeography (Velasquez et al., 2018), although its effect can be only marginal (Ávila et al., 2018). However, the hypothesis of higher speciation rates on larger islands, seems not to be so important for marine organisms. Their larger dispersal capacity hamper intra-island allopatric speciation, so in situ cladogenesis is low. A study of endemic reef fish in the seamounts and islands

Fig. 3 Variation of marine shallow-water species richness with islands area (A–C), age (D–F) and isolation (G–I) for 11 oceanic islands in the Atlantic Ocean. Figure from Hachich N. F., Bonsall M. B., Arraut E. M., et al. (2016). Marine island biogeography. Response to comment on ‘island biogeography: Patterns of marine shallow-water organisms’. *Journal of Biogeography* **43**, 2517–2519.

of the Vitória-Trindade Chain (VTC), South-western Atlantic, showed evidences that speciation rates increased with the accumulation of species with low dispersal capacity, that suffered differentiation after immigration (Pinheiro et al., 2017). Speciation of marine shallow-water organisms in islands will be deeper discussed below.

Species–isolation relationship

The distribution of either marine or terrestrial organisms are influenced by geographical barriers, whose permeability is felt distinctively between the two realms. The seas represent a semipermeable matrix for the immigration of species to islands and the dispersion of organisms from one island to the other. For marine organisms such matrix is much easier to transpose than for terrestrial ones, mainly due to their resistance to water and salt. A study showed that terrestrial plants, which dispersal is within the widest from terrestrial groups, disperse one to two orders of magnitude less than sedentary marine species (Kinlan and Gaines, 2003).

Most marine shallow-water organisms, although sedentary when adults, have a planktotrophic larvae or other planktonic propagule stage on its life cycle. This capacity to live or even feed or photosynthesize while floating in the water surface favors dispersal through ocean currents (Thorson, 1949). Those marine organisms without a planktonic stage can have their dispersal facilitated through rafting. This is especially important for small-sized organisms that have the ability of attaching to migratory animals (e.g. birds or sea turtles) or drifting substrates (e.g. trunks or seaweeds). Rafting was shown to be an important mean of dispersal to marine shallow-water organisms through biogeographic barriers (Luiz et al., 2011). An overview on this subject pointed out for 946 species of marine invertebrates with clues of rafting (Table 1; Thiel and Gutow, 2005). The colonization of the reef fish *Chromis limbata* in the southern brazilian coast was probably a consequence of rafting of specimens from the Macaronesian region through the Atlantic Ocean—although other hypotheses are also discussed (Anderson et al., 2017), and the dispersal of the seastar *Patiriella exigua* is also suggested to occur via rafting on macroalgae (Waters and Roy, 2004).

Such wide dispersal capacity has implications to marine island biogeography. The IBT postulates that species richness is expected to decrease in function of island isolation due to reduced immigration rates. Although small coastal islands present higher diversity of reef fish species than larger oceanic islands (Pinheiro et al., 2015), for marine shallow-water groups, the species–isolation relationship seems to be not universal, but highly scale- and taxon-dependent (Fig. 3G–I). For example, in oceanic islands of the Atlantic Ocean the species-isolation pattern was detected for gastropods and seaweeds, but not for reef fishes (Fig. 3; Hachich et al., 2016) and echinoderms (Ávila et al., 2018). However, even for gastropods and seaweeds, the role of isolation on bounding species richness in the Atlantic islands seems to be secondary, as island area was by far the best model on explaining such richness variation (Hachich et al., 2015, 2016). On the other hand, at a smaller spatial scale, across the Lusitanian Macaronesia, seaweeds species richness decreases with distance from mainland when considering green, red or brown algae together or separately (Tuya and Haroun, 2009). Such variations in the influence of island isolation within marine shallow-water groups are also due to variations in species dispersal capacity. It was shown that while seaweeds dispersal ranges from few meters to 5 km, reef fish dispersal ranges from few to several hundreds of kilometers, and, finally, the dispersal of marine invertebrates varies from tens of meters to hundreds of kilometers (Fig. 4; Kinlan and Gaines, 2003).

Studies on large spatial-scale showed contrasting conclusions about the influence of isolation on reef fish species richness (Mora et al., 2003; Parravicini et al., 2013; Jacquet et al., 2017). The differences between these studies were their study area and the isolation metric used. Mora et al. (2003) included only the Indo-Pacific and showed a strong influence of the distance from the Coral Triangle (biodiversity center) on species richness. The two other studies spanned worldwide. Parravicini et al. (2013) found an extremely weak influence of isolation on reef fish species richness and used two measures of connectivity: (i) the relative proximity of each site to patches of reef fish habitat, using a nearest neighbor approach, and (ii) the distance of the site from the mid-domain, relative to the domain size. Finally, although Jacquet et al. (2017) showed a significant decrease of reef fishes with isolation ($p < 0.05$), they also showed that their isolation measure (based on nearest neighbor approach) was negatively correlated with reef area.

Those results highlight an important issue when investigating the influence of isolation on biodiversity, that is the measure of isolation used. Not only the distance to species sources and present ocean currents can influence connectivity between marine

Table 1 Number of species with evidence of rafting dispersal per marine invertebrate taxon.

<i>Taxon</i>	<i>Number of spp.</i>
Porifera	3

habitats. Past ocean currents, presence of stepping-stones (islands and seamounts), sea level variation and distance to Quaternary coral reef refugia are other variables to be considered when studying marine shallow-water distributional patterns (Pellissier et al., 2014; Brown and Lomolino, 2006). The high species richness found in Trindade Island, for instance, is related to the presence of a seamount chain between the island and the continental coast, which was exposed during the low sea-level periods of the Pleistocene (Pinheiro et al., 2017; check the methodological caveat section for more examples).

Species–age relationship

The age of an island has also been shown to influence marine shallow-water species richness (although studies on marine species–age relationship are scarce). In a large-scale analysis of oceanic islands in the Atlantic, the species richness of seaweeds, gastropods and reef fishes were strongly correlated with islands geological age (Fig. 3). Moreover, when islands area, age and isolation were considered, age showed to be the best predictor of reef fish richness—although it was the worst predictor for seaweeds, reinforcing the taxon-dependency in marine shallow-water island biogeography patterns (Hachich et al., 2015). Still, the richness of epibiont species on pumice rafts also showed an influence of pumices age—measured as numbers of days since eruption (Velasquez et al., 2018).

The explanations for the marine shallow-water species-age patterns are equivalent for those of terrestrial biota, such as longer time for species accumulation by immigration and speciation (Hachich et al., 2015; Whittaker and Fernandez-Palacios, 2007). Moreover, the increase of island area through time (Whittaker et al., 2008; Ávila et al., 2019) can also intensify the relationship between islands age and species richness and will lie upon the life cycle of an oceanic island.

Multivariables models for species richness

The present geographical distribution of biodiversity in islands is expected to be a result of ecological, evolutionary and historical forces acting in different timescales. The GDM, explained above, is an attempt to incorporate to the IBT those processes operating in large timescales, and therefore, includes on a single model, island area and age as species richness predictors (Whittaker et al., 2008).

Although tests of this model proved it to be adequate for the terrestrial biota, it seems not to be satisfactory on explaining marine shallow-water biodiversity. For example, the GDM did not explain the richness variation of reef fish, gastropod, seaweed and echinoderm species in the Atlantic better than when considering only area or age as predictors variables alone (Hachich et al., 2015; Ávila et al., 2018).

To discuss the applicability of GDM to the marine realm with assertion, additional tests would be needed, including other taxa, biogeographic regions or spatial scales. Anyway, due to differences on the impact of island ontogeny on terrestrial and marine habitats, adaptations for the GDM model to embrace marine organisms are indeed necessary and are already being suggested. The main adaptation regards the influence of time in marine habitat area. As cited before, the GDM assumes that the erosion of islands enhances habitats heterogeneity on an initial stage, but drastically reduces it on advanced stages of erosion (Whittaker et al., 2008). However, longer times of erosion are needed for islands to reach a stage in which marine habitat heterogeneity starts to decrease, and so the species richness (Fig. 5). In fact, the seamount stage, achieved when islands are extremely old, is the one with greater marine area availability—but not necessarily the higher marine shallow-water species richness (Hachich et al., 2015; Pinheiro et al., 2017; Ávila et al., 2019).

The Vitória-Trindade Chain Model (VTCM; Pinheiro et al., 2017) and the Sea-Level Sensitive dynamic model (SLS; Ávila et al., 2019) are both models that comprise the effect of island ontogeny into marine systems processes, and show differences of predicted immigration, extinction and speciation rates if compared to the GDM. Those, in turn, result in differences on the estimated species richness and the system carrying capacity (Fig. 5). Notwithstanding, the SLS also comprises a more complex relationship of marine

Fig. 5 Graphical representation of Immigration (I, green lines), Extinction (E, red lines) and Speciation (S, blue lines) rates of (A) the General Dynamic Model (GDM) of oceanic island biogeography; (B) the Sea-Level Sensitive (SLS) model of marine island biogeography; and (C, D) the Vitória-Trindade Chain general dynamic model (VTCM) of oceanic island biogeography for marine species, in which (C) immigration, extinction and speciation rates are only related with time (evolutionary history of the island—geological timescale) or (D) immigration, extinction and speciation rates are occurring in an ecological scale, strongly related to richness. For all models, K (black bold line) is the potential carrying capacity measured in species number, and R (black line) is the realized species richness. Adapted from Whittaker R. J., Triantis K. A., and Ladle R. J. (2008). A general dynamic theory of oceanic island biogeography. *Journal of Biogeography* **35**, 977–994; Pinheiro, H. T., Bernardi, G., Simon, T., et al. (2017). Island biogeography of marine organisms. *Nature* **82**, 82–86. and Ávila, S. P., Melo, C., Berning, B., et al. (2019). Towards a 'sea-level sensitive' dynamic model: Impact of island ontogeny and glacio-eustasy on global patterns of marine island biogeography. *Biological Reviews of the Cambridge Philosophical Society* **94**, 1116–1142.

habitat heterogeneity and time, due to sea-level changes during glacial periods (Fig. 5; Ávila et al., 2019). Although neither the VTCM nor the SLS make predictions on how species richness must vary with islands features (such as area, age or isolation), they give important insights for the discussion of immigration, extinction and speciation rates of marine biota in islands (Fig. 5).

Functional Approach on Island Biogeography

The studies on biodiversity distribution patterns through time and space have originally considered only species richness as a measure of biodiversity (Gotelli and Colwell, 2001). The theories of island biogeography, for example, deal mainly with species counts. However, the foreseen equilibrium between immigration, extinction and (for some models) speciation rates, although predicts a stable species richness to be held by an island, also predicts a constant species turnover (MacArthur and Wilson, 1967; Whittaker et al., 2008). Little is known whether other biodiversity components than species richness would also remain constant or would vary through this turnover.

On relying on species richness solely, these theories consider species as being equivalent, disregarding their intrinsic features. Species phenotypic traits have been related to potential ecological functions played in the ecosystems (Mouchet et al., 2010). Such traits can be classified by morphological, behavioral and trophic characteristics (Mouillot et al., 2014). Through the combination of them—for example, body size, diet, and grouping behavior—it is possible to classify species on functional groups and, therefore, infer the community's functional richness.

Island systems show singular environmental features that could lead to nonrandom processes over its biota composition. Mechanisms like environmental filtering and competitive exclusion can favor functional traits by selective extinction (Si et al., 2017) or immigration (on the perspective of regional processes). The selective extinction or immigration caused by environmental filters would result on a higher functional similarity, that is, a functional clustering, while the selective extinction caused by competitive exclusion would result on lower functional similarity, that is, a functional overdispersion (Cavender-Bares et al., 2009; Si et al., 2017; Fig. 6).

Fig. 6 Expected functional island biogeography patterns. The color and shape of symbols express the similarity in functional traits, where shape represents a categorical trait value and color a continuous trait value. F Diverg is a hypothetical measure of functional divergence between species. (A) Regional environmental conditions would cause a selective immigration, preventing the arrival of species with (or without) certain functional traits. Similarly, local environmental conditions would cause a selective extinction, eliminating species whose traits are unfavorable to these conditions. These selective immigration or extinction as result of environmental filtering would cause a clustering on the functional space and is expected to be more intense on smaller and more isolated islands, intensifying the clustering pattern with reducing area and increasing isolation. (B) Local competitive exclusion would cause a selective extinction, eliminating ecologically similar species and causing a functional overdispersion. This overdispersion intensity would decrease with islands area and increase with island isolation, due to the reduced habitat heterogeneity and rescue effect, respectively. (C) On the prevalence of neutral processes, there would be no selective immigration or extinction, so these processes would be random, and no patterns of varying functional overdispersion or clustering with islands area or isolation would be observed. Adapted from Si, X., Cadotte, M. W., Zeng, D., et al. (2017). Functional and phylogenetic structure of island bird communities. *Journal of Animal Ecology* **86**, 532–542.

On the assumption of an increasing habitat complexity with area, the effects of environmental filtering or competitive exclusion are expected to be more prominent on smaller islands. Given that, on the presence of local environmental filters, smaller islands would show even more functional clustering than bigger islands. In the same way, on the advent of competitive exclusion, the functional overdispersion will be stronger on smaller than on bigger islands (Fig. 6).

The IBT also predicts isolated islands to have lower immigration rates and, consequently, show reduced species richness (MacArthur and Wilson, 1967). Again, no assertions were made whether these immigration events are random regarding species functional traits (Whittaker et al., 2014). The challenges to achieve a remote island are tougher, as there is more chance for facing physical and environmental barriers in the way. Therefore, affected by regional environmental filtering, isolated islands would show even higher functional clustering than more connected ones (Fig. 6). Moreover, on the assumption of a reduced rescue effect on more isolated islands, the outcomes of competitive exclusion would be more intense, as the species are not receiving inputs of individuals from source communities, that could soften the extinction rates. Therefore, the functional overdispersion would increase with island isolation (Si et al., 2017; Fig. 6).

Finally, regarding island age, Borregaard et al. (2017) included a functional approach to the original General Dynamic Model of Oceanic Island Biogeography (GDM), but, again, focusing on terrestrial systems. According to them, young islands, on an initial stage of colonization, would hold a reduced pool of functional traits. These traits variability would increase with speciation events while the island is increasing in habitat heterogeneity. However, on its most advanced stage, habitat loss caused by excessive erosion would imply into lower niche availability, causing selective extinction of species with specialized traits and, also, intensifying extinction rates of those with similar traits—as a result of stronger competition between ecologically similar species (Borregaard et al., 2017).

Functional island biogeography for marine shallow-water species

To our knowledge, there are no studies relating marine shallow-water functional richness to islands features, although a few studies relates single marine shallow-water biota traits to islands area and isolation. Jacquet et al. (2017) proposed two process-based models including the functional component of biodiversity into the IBT. The Allometric Theory of Island Biogeography (ATIB) treats mainly of the variation on species body-size with island area and isolation, while the Allometric and Trophic Theory of Island Biogeography (ATTIB) emphasizes the importance of species trophic level together with body size (Jacquet et al., 2017).

On what concerns selective immigration, it is known that species dispersal ability influences their immigration capacity, so that weak dispersers would be almost absent in remote islands. In marine systems, functional traits like pelagic larval duration (PLD),

species body size, grouping behavior and nocturnal activity have been related to dispersal capacity (Reaka, 1980; Shanks et al., 2003; Mora et al., 2003; Luiz et al., 2013; Stier et al., 2014). For instance, larger coral-dwelling mantis shrimp species show a wider longitudinal span (Reaka, 1980). Likewise, a study on reef fish distributions through 134 tropical reefs across the globe showed an increase of species mean body size with isolation (Fig. 7B; Jacquet et al., 2017). Reef fish body size was also showed to be a predictor of their capacity to cross both the Mid-Atlantic and the Amazon-Orinoco Plume barriers in the Atlantic Ocean, mainly due to the faster growth rate of large species, which reduces the risk of predation while dispersing (Luiz et al., 2011). Still, reef fish species recorded in oceanic islands of the southwestern Atlantic are positively related to rafting use, great depth ranges and large body sizes, while their endemism is mainly related to small body sizes (Pinheiro et al., 2018). Exceptions for that would be for cases

Fig. 7 Relationship between body sizes and reef area and isolation for piscivorous (black circles) and herbivorous (gray crosses) reef fish on 134 tropical reefs across the world. The lines illustrate significant ($p < 0.05$) relationships between the variables. Piscivorous and herbivorous mean body size (A) decreased with area and (B) increased with isolation. (C) The standard deviation (SD) of body size increased with area only when piscivorous fish were considered, showing that larger areas hold a greater variability of piscivorous fish body size. Figure from Jacquet, C., Mouillot, D., Kulbicki, M. and Gravel, D. (2017). Extensions of Island Biogeography Theory predict the scaling of functional trait composition with habitat area and isolation. *Ecology Letters* **20**, 135–146.

such as the VTC, in which an evolutionary path toward reduced reef fish dispersal capacity was followed through an anagenesis speciation process (Pinheiro et al., 2017), as a relationship between species evolutionary age and dispersion capacity was evident.

On what concerns selective extinction, species with generalist diets are expected to be less vulnerable to extinction than others with restricted diets, especially on smaller islands, in which resources are more limited. Although Jacquet et al. (2017) found no differences between piscivorous and herbivorous fish species-area and species-isolation patterns on islands (Fig. 7A–D), they verified a higher prevalence of extreme reef fish body sizes on larger areas only when piscivorous fish were considered (Fig. 7E). That is, while larger islands show variable sizes of piscivorous species, the smaller islands show a prevalence of fish species with intermediate mean body sizes. The explanation for this pattern relies on the relationship between the species body size, trophic group and extinction and immigration rates of this taxon. Reef fish intermediate-sized species are less susceptible to extinction than those with extreme body sizes, due either to their more generalist diet, when compared to smaller species, or to the maintenance of higher population densities, when compared to larger species (Jacquet et al., 2017). Therefore, the piscivorous fish, on being more specialist and therefore even more susceptible to extinction (if compared to herbivorous species), presented a pattern of increasing size standard deviation with island area (Fig. 7E).

Therefore, when comparing the ATIB and ATTIB, the latter, by also including the species trophic level as an important functional trait, was shown to be a better model than the ATIB (that included only species body size) on explaining reef fish distributions across the globe (Jacquet et al., 2017). However, although either the ATIB and ATTIB give important insights to functional island biogeography, generalizations to other marine shallow-water groups must bear in mind taxa specificity on the relationship between body size, trophic level and extinction and colonization rates (Jacquet et al., 2017).

On what concerns island age, although no tests on the GDM functional approach were done to marine biota yet, we would expect that adaptations equivalent to those proposed for taxonomic marine shallow-water GDM would be necessary, due to the increased marine shallow-water habitat area of islands on advanced erosion phases.

Speciation and Endemism Patterns in Marine Shallow-Water Habitats

Speciation is an evolutionary process that consists in the formation of one or more descendent species from an ancestral one (Mayr, 1947). Despite the advances in the knowledge about the origins of the terrestrial biodiversity, the understanding of how new species arise in marine habitats is still poorly known (Bowen et al., 2013). Major differences are related to the few opportunities for geographical isolation in a circumglobal aquatic medium, where few obvious physical barriers are present and for which most organisms have a pelagic larvae stage with a high dispersal potential. Anyway, an average of 42% of “endemism” can be seen within each marine realm—benthic molluscs and arthropods contribute the most for this endemism—so that major biogeographic barriers constrain species distribution worldwide (Costello et al., 2017). But, in general, many marine populations are genetically connected among different ocean basins, as it is the case for many pelagic and bathypelagic fish species (Gaither et al., 2016), the brown algae *Dictyota ciliolata* and *D. crenulata*, among other species that display a circumtropical distribution (Tronholm et al., 2012). Therefore, the combination of few physical barriers and high dispersal capacity reduces opportunities for allopatric speciation—classical model where populations become isolated due to the rise of physical barriers and end up in different evolutionary paths (Rocha et al., 2005). However, since many marine habitats (e.g. reefs, estuaries, kelp forests, sand beaches) shelter high biodiversity levels—some of them comparable to the highly diverse rainforests—the generalization that speciation must be rare in taxa with high dispersal capacity is inaccurate (Rocha et al., 2005; Pinheiro et al., 2017; Delrieu-Trottin et al., 2019).

Speciation in marine systems has been explored in biodiversity hotspots—e.g., Coral Triangle in the Indo-Pacific and the Caribbean—where richness levels are explained by three main hypotheses (Bowen et al., 2013). The first considers biodiversity hotspots as “Centers of origin,” where intensive competition among species would promote the emergence of new species (Briggs, 2003). According to this hypothesis, species originated in the biodiversity center could colonize marginal provinces and evolve in different species (Bowen et al., 2013). The second hypothesis, known as “Center of accumulation,” suggests that new species arise in peripheral areas, such as oceanic islands and archipelagos, and then colonize and accumulate in biodiversity hotspots, with the aid of prevailing currents (Kool et al., 2011). Some cases involve a biodiversity feedback process, where species migrate from biodiversity hotspots, evolve in a different species in the periphery, and finally colonize back the original province (Bowen et al., 2013). For instance, the Ember parrotfish (*Scarus rubroviolaceus*) and the Yellow tang (*Zebrasoma flavescens*) occur in the Indo-Pacific region, however population genetic data indicates that their ancestral lineage had first colonized and evolved in Hawaii, spreading back to the central Pacific later (Eble et al., 2011; Fitzpatrick et al., 2011). Finally, the “Center of overlap” hypothesis suggests that the high species richness observed in biodiversity hotspots is the result of different communities overlap, which were previously divided by historical events, such as changes in the sea level (Gaither and Rocha, 2013; Pinheiro et al., 2017) and movements of tectonic plates (Leprieur et al., 2016). In the Atlantic Ocean and in the Coral Triangle, low sea-levels intensified biogeographic barriers for marine organisms due to land exposing, reducing gene flow and driving allopatric speciation (Rocha et al., 2005; Floeter et al., 2008; Gaither and Rocha, 2013). In higher sea level stands, species expanded their distribution and overlapped in the biodiversity hotspot. However, sea-level oscillations played different roles on driving speciation, depending on the availability of shallow habitats. In the VTC, southwestern Atlantic, for example, low-stand sea levels, instead to promoting vicariance, allowed dispersal from mainland to the arising seamounts (Pinheiro et al., 2017), similarly to the effect of low sea levels in improving terrestrial connectivity. In summary, the Center of origin hypothesis involves speciation without complete geographic isolation—i.e., parapatric and sympatric speciation—while the Center of accumulation and the Center of Overlap hypotheses include some level of vicariance and isolation—i.e., allopatric or peripatric speciation. These hypotheses put oceanic islands in

opposing roles in what concerns marine shallow water biodiversity, since for the Center of origin model, islands are evolutionary dead ends for some species, whereas in the Center of accumulation and Center of overlap, islands are cradles of biodiversity (Bowen et al., 2013).

On contrasting terrestrial and marine realms, endemism is much more common on land than in the sea, again, due to the high dispersal capacity of marine organisms, allowing a greater connectivity between populations and, therefore, reducing extinction and speciation rates (Pinheiro et al., 2017; Ávila et al., 2019). For example, endemism levels for reef fish in the Atlantic Ocean, even considering its most isolated oceanic islands (Ascension and Saint Helena), varied from 0% to 13.2% (Hachich et al., 2015; Floeter et al., 2008). Conversely, in the Atlantic islands, the endemism of terrestrial plants—group within the ones with higher dispersal ability in land—ranged from 7.2% to 40% (Whittaker et al., 2008; Emerson and Oromí, 2005).

Another interesting contrast between the terrestrial and marine biotas is that isolated archipelagos are functionally “islands” for most marine species. Speciation within islands in a given archipelago is commonplace for terrestrial species, while in the sea it can be very uncommon. For example, while the speciation of tortoises and finches in the different islands of the Galapagos is well known (Román-Palacios and Wiens, 2018), endemic reef fishes there are spread over the entire archipelago (Bernardi et al., 2014). Despite the relatively lower rate of endemic shallow-water species in the ocean, there are 18 marine centers of endemism, which together, embrace > 50% of the world’s restricted-range species of fishes, corals, snails and lobsters (Fig. 8). Such centers are mainly composed by groups of islands that, although distributed across all the oceans, prevail in the Indo-Pacific region (Roberts et al., 2002).

Endemism relies into specific spatial and temporal boundaries. Geographic or ecological characteristics allow the delimitation of an area that encompass the distribution of an endemic species, while the evolutionary history of a species allows its classification as a new or an old endemic (Anderson, 1994). Neoendemic species would occupy a restricted area due to their recent origin, while paleoendemism would be the remnants of a more widespread ancestral species (Tedesco et al., 2012). In practical terms, paleoendemic species could be distinguished from neoendemism as the formers display deep divergence times from their sister species together with signals of distribution contraction (Cowman et al., 2017). Oceanic islands appear to harbor a combination of paleo and neoendemic species (Fig. 9; Cowman et al., 2017; Pinheiro et al., 2017; Delrieu-Trottin et al., 2019). The marine gastropod genus *Conus*, for instance, suffered an explosive radiation in Cape Verde during the last few million years, resulting in > 40 neoendemic species in the archipelago (Duda and Rolán, 2005; note that this within-archipelago speciation is an exception for marine organisms). On the other hand, the Trindade parrotfish *Sparisoma rocha* and the wrasse *Halichoeres rubrovirens* had their ancestral lineages extinct from the continental coast, only remaining in the VTC, that serves as a museum for these old lineages (Pinheiro et al., 2017). However, most endemic fishes of the VTC are indeed neoendemism (Fig. 9), with limited dispersal potential, which colonized the most distant islands when the sea-level was lower than today, exposing seamounts that acted as stepping stones. The sea-level rise created a vicariant barrier and contributed to speciation (Pinheiro et al., 2017). Therefore, the speciation scenario in the VTC follows the premises of the IBT, where good dispersers colonize distant islands first, and weak dispersers later. These good dispersers evolve by parapatric and ecological speciation, while the weak dispersers, if do not get extinct, evolve by allopatric or peripatric speciation. In the most extreme example of island isolation, the Easter Island shows one of the highest endemism levels of marine species in the world, with nearly 22% for reef fishes (Randall and Cea, 2011). The evolutionary history of Easter Island endemics also shows a majority of neoendemism with restrict geographic range, together with a few wide distributed older endemics (Delrieu-Trottin et al., 2019).

Our knowledge about the drivers of marine endemism patterns is still in its infancy, and few information is available regarding the variation of marine shallow-water endemism with islands area, age and isolation. The GDM foresees for the proportion of endemism the same trend behavior as for the variation on species richness with area and age. That is, endemism would increase linearly with area and as a unimodal function of age (Whittaker et al., 2008). Although this has been observed for terrestrial organisms (Whittaker et al., 2008; Cameron et al., 2012; Triantis et al., 2015), the GDM is not a good model for marine gastropod and reef fish endemism in the Atlantic (Hachich et al., 2015; Ávila et al., 2018). In fact, among the two groups, only gastropod shows an increase of endemism with area (Fig. 10B). Moreover, it seems to be no relation at all between reef fish and gastropod endemism with island age (Fig. 10A; Hachich et al., 2015; Ávila et al., 2018). Finally, only reef fish endemism varied with island isolation (positive relationship; Fig. 10C). Despite its high dispersal ability, reef fishes exhibit a high auto-recruitment, especially for endemic species (Robertson, 2001), which can also influence endemism spatial patterns.

Fig. 8 The 18 multitaxa centers of marine endemism, considering fishes, corals, snails and lobsters. Figure from Roberts, C. M., McClean, C. J., Veron, J. E. N, et al. (2002). Marine biodiversity hotspots and conservation priorities for tropical reefs. *Science* **295**, 1280–1284.

Fig. 9 Proportion of reef fish endemic species found in different oceanic islands across the marine biogeography regions. Size of circles indicates the proportion of the assemblage made up by endemic species. Colors show the different types of endemism observed in oceanic islands: neo-endemics (blue, ≤ 2.6 Ma), paleo-endemics (orange, > 2.6 Ma). Data was extracted from Cowman P. F., Parravicini V., Kulbicki M., and Floeter S. R. (2017). The biogeography of tropical reef fishes: Endemism and provinciality through time. *Biological Reviews* **92**, 2112–2130; Pinheiro, H. T., Bernardi, G., Simon, T., et al. (2017). Island biogeography of marine organisms. *Nature* **82**, 82–86, and Delrieu-Trottin, E., Brosseau-Acquaviva, L., Mona, S., et al. (2019). Understanding the origin of the most isolated endemic reef fish fauna of the Indo-Pacific: Coral reef fishes of Rapa Nui. *Journal of Biogeography*. doi:10.1111/jbi.13531.

Fig. 10 Variation of marine shallow-water endemism with islands (A) age, (B) area and (C) isolation for reef fish and marine gastropod. Reef fish data are from 15 islands in the Atlantic and Tropical Eastern Pacific plus Easter Island (compiled from Robertson, 2001, Floeter et al., 2008, and Hachich et al., 2015). Gastropod data are from eight island in the Atlantic Ocean (obtained from Ávila et al., 2018). Only significant ($p < 0.05$) regressions lines were presented.

Methodological Caveats for Marine Shallow-Water Island Biogeography

The study of marine habitats, for those that are used to study the terrestrial biota, would be, in some ways, equivalent as looking to the world on an upside-down vision. Thus, adaptations to conventional research methods developed based on terrestrial studies are needed. Regarding island biogeography, except for the VTCM (Pinheiro et al., 2017), SLS (Ávila et al., 2019) and the ATIB and ATTIB (Jacquet et al., 2017), that were specially (and recently) designed for the marine biota, other theories and amends were conceived based on the terrestrial realm. Therefore, attention is required when bringing island biogeography to the marine sphere, either related to the measures of islands features—such as area, age and isolation—or to the limits to line off marine communities.

A first point of concern is related to island definition. For marine shallow-water organisms, depending on the scale of analysis, even a shipwreck or a small group of rocks can be treated as an island. On the other hand, for large spatial scale analysis, given the higher dispersal capacity of most of these organisms, a whole archipelago could be treated as a single island—in the sense that its component islands and islets show great within-island biota affinities. For sure such island definition must bear in mind taxon features specificity and the component of biodiversity being analyzed, as little is known about the distribution of functional groups within-islands in archipelagos.

When accounting for island area, although some authors have considered the emerged island area or coastal perimeter as a proxy for the real habitat area available for marine shallow water organisms (e.g. Tuya and Haroun, 2009), islands shallow shelf area would be, by far, a better unit of measure. The slope of an island aid on determining the availability of shallow shelf habitats, so that steeper surfaces imply in smaller areas. The terrain steep above and below water are not necessarily equivalent, especially for old islands on a high degree of erosion, which display a higher shallow water area compared to emerged area (Ávila et al., 2019). The shallow shelf surface of marine systems can be obtained by bathymetry from nautical charts or satellite data.

Another concern related to island area is that glacial periods were shown to have impacted the slope of islands terrain and their habitat variability directly, by selectively wiping out substrates such as beach sand (Ávila et al., 2019). And because islands shelf-break are generally shallower than continental ones, sea-level reduction would have hugely impacted their total available shallow area during glacial periods. Given that, also the past shallow shelf surface availability could have influenced the actual islands biodiversity, particularly when considering their functional diversity.

Another important discussion is about down to which depth to consider as shallow. Traditionally, shallow-water habitats are those down to depths of 200 m, just before the continental slope (Lalli and Parsons, 1997). However, authors have defined different depths for shallow-water organisms, even when the same taxon is being considered. For instance, although sponge richness increases with depth (Alcolado, 1994), depths limits from 10 to 30 m have been applied for sponge shallow-water studies (Longakit et al., 2007; Lim et al., 2012; Hadi et al., 2018; Ávila et al., 2011). On a quick literature overview, maximum depths delimitations for shallow-water organisms varied from 6 to 200 m deep (Sangil et al., 2018; Ávila et al., 2011; Edgar et al., 2004; Villaça and Pitombo, 1997; Flórez et al., 2018; Floeter et al., 2008), and a few papers did not even use a depth limitation. Whether this definition should rely on an arbitrary depth limit or be related to each taxon ecology, a standardization for the phrase, or at least a better definition in each paper—based on scientific arguments—would allow better grounded syntheses and multiple studies comparisons. For instance, there are evidences of a high malacofauna turnover about the 50 m isobath (Ávila et al., 2019) and the 30 m depth isobath was showed to be a transitional zone between reef fish shallow and deep species composition (Brokovich et al., 2008).

Measuring island isolation as a geographical parameter, is not that challenging, although measuring the real isolation between communities can be tricky, especially when considering marine organisms. Originally, the IBT has been measuring island isolation as the distance from mainland or even the distance to the nearest larger suitable habitat. These isolation measures rely on the source-sink dynamic model (Pulliam, 1988), in which larger areas, with high quality habitats, serve as source of species to smaller areas (impoverish habitats), such as islands. The distance from a hotspot can also be used as a measure of isolation, based on the “Center of origin” hypothesis on marine shallow-water biodiversity. However, especially when considering the “Center of accumulation” or “Center of overlap” hypotheses, in which islands are cradles of biodiversity, more complex measures of isolation, that consider the mosaic of suitable habitats in which the island is located, needs to be applied.

Finally, islands age measures are tricky to determine, mainly because islands can span long periods of formation—eastern Azores islands, for example, show rock fragments dated between 0.95 and 8.12 millions of year from the present (Abdel-Monem et al., 1975). The oldest age in which an island has reached a certain shallow water depth (again, depending on shallow-water definition) would be a reasonable estimate of the availability for colonization. Technology has advanced toward facilitating access to many of these data, so that IBT studies is expected to improve in accuracy and quality.

Abstract

The passing of the 50th anniversary of the theory of island biogeography (IBT) has helped spur a new wave of interest in the biology of islands. Despite the longstanding acclaim of [MacArthur and Wilson's \(1963, 1967\)](#) theory, the breadth of its influence in mainstream ecology today is easily overlooked. Here we summarize some of the main links between IBT and subsequent developments in ecology. These include not only modifications to the core model to incorporate greater biological complexity, but also the role of IBT in inspiring two other quantitative theories that are at least as broad in relevance—metapopulation theory and ecological neutral theory. Using habitat fragmentation and life-history evolution as examples, we also argue that a significant legacy of IBT has been in shaping and unifying ecological schools of thought.

Recent years have seen a surge in interest in island biology and island biogeography theory (IBT; [Losos and Ricklefs, 2010](#); [Santos et al., 2016](#); [Patino et al., 2017](#); [Whittaker et al., 2017](#)), partly motivated by the 40th and 50th anniversaries of the Core IBT model ([MacArthur and Wilson, 1963](#)) and the monograph that expanded on this model with related ideas ([MacArthur and Wilson, 1967](#)). We were involved in one such initiative, a working group on island biogeography funded by the Centre for the Synthesis and Analysis of Biodiversity (CESAB). A major output of the group was a collective perspective on how key attributes of islands surrounded by water provide prospects for improving our understanding of the ecology and evolution of biological communities in general ([Warren et al., 2015](#); see Box 1 for a detailed distinction of IBT and Core IBT). In the process of organizing our ideas, interesting issues arose that were tangential to this aim. One example is that over the decades since 1967, IBT has inspired numerous ecological theories and schools of thought. Although IBT is focussed on islands surrounded by water, even in the opening pages of the 1967 monograph, MacArthur and Wilson emphasized that such island biomes are an extreme example of fragmented or insular environments (isolated by geography or ecology) that are common worldwide. Consistent with this view, not only has IBT proven relevant to a wide variety of insular environments that are not islands surrounded by water (e.g., [Brown, 1971](#); [Drake et al., 2002](#); [Wagner et al., 2014](#)), but it also has links to important ecological theories and concepts, the implications of which stretch far beyond such islands.

Here we highlight some of the main links between IBT and subsequent developments in ecology and conservation biology.

The elegance of Core IBT stands in its ability to model complex phenomena with few parameters. Diversity dynamics on an island incorporate a simple birth and death process in which births represent species arriving through immigration and deaths represent local (i.e., island-wide) extinctions; Core IBT predicts that diversity will tend toward a “dynamic equilibrium” in which these processes are balanced. These ideas predict considerable variation in local community composition due to the stochasticity of immigration and local extinction, and the time taken to reach equilibrium (see also [Warren et al., 2015](#), Box 6, for related situations with unattained equilibria). Nonetheless, Core IBT provides a highly deterministic perspective on species richness based on the assumption that the rates of immigration and extinction are determined by the geographic context: near islands have a higher rate of immigration than far islands, and small islands have a higher rate of extinction than large islands. Accordingly, other things being equal, diversity should be highest on islands that are large and close to the mainland, and lowest on islands that are small and far.

The “island biome” (islands surrounded by water) is an obvious choice for studying the effects of area and isolation on species richness since insularity is acute; an island’s boundaries frequently provide longstanding limits to the distributions of species or populations (see [Warren et al., 2015](#) for further discussion, including key attributes of islands). Nonetheless, in addition to the predominance of other insular and fragmented environments worldwide, small habitat islands are among those most easily studied and manipulated. Such practical constraints are reflected in the range of systems in which the equilibrium predictions of Core IBT have been tested ([Schoener, 2010](#)), which include fragmented crops and intertidal habitats, as well as islands surrounded by water. Application of Core IBT to insular systems that are not “true islands” arguably reached an extreme in the design of protected areas, such as the debate over whether a single large, or several small, reserves is better for ensuring the persistence of species (“SLOSS” for short). Problems with this approach include the fact that Core IBT does not generate clear predictions in this matter ([Simberloff and Abele, 1982](#)), and also that for habitat islands, unlike “true islands”, an organism’s ability to inhabit, or disperse through, the intervening matrix is a critical factor. In the end, ecologists concluded that Core IBT provides only limited practical lessons for conservation managers ([Soulé and Simberloff, 1986](#)). Nonetheless, by forcing decision makers to think about population turnover within habitat fragments, as well as the influence of fragment size and isolation on colonization and extinction, a highly diversified field of fragmentation research can be traced back to Core IBT ([Laurence, 2010](#)).

A more direct example of the relevance to IBT of insular systems that are not “true islands” comes from an extension to the Core IBT model to improve its ability to predict species diversity. At low isolation, the frequent arrival of propagules protects insular populations from extinction. This “rescue effect” was first demonstrated empirically for arthropods on isolated plants (thistles; Brown and Kodric-Brown, 1977). Other examples of modifications to Core IBT include adding the effect of island habitat heterogeneity on colonization and extinction dynamics (e.g., Johnson et al., 1968; Whitehead and Jones, 1969; Kadmon and Allouche, 2007), as well as the effects of changes in the physical geography of islands over time (Whittaker et al., 2008). Recent developments have extended this legacy by showing how, without adding much complexity to the original model, species interactions could easily be incorporated with important consequences for the shape of the species-area relationship (Gravel et al., 2011) or even for the number of trophic levels expected in fragmented systems (Holt et al., 1999; Calcagno et al., 2011). For example, predator-prey interactions may slow down species accumulation with area, while mutualistic interactions may accelerate it. Realizing such multitrophic extensions to Core IBT was key in the development of recent theories of community assembly and codistribution in isolated habitats (Cazelles et al., 2015, 2016). Furthermore, some of the main parameters of Core IBT have sometimes been modified to provide new interpretations, as in Wright’s (1983) replacing area with available energy to develop a species-energy theory.

Another important extension of IBT was to consider the dynamics of populations on multiple islands (metapopulations) connected by movements of individuals. Although IBT and metapopulation theory (Levins, 1969, 1970) were not formally connected initially, their relationship can be traced back to an agreement among their authors to work on complementary questions, MacArthur and Wilson’s being “how many species does an island contain?” and Levins’ being “how many islands does a species occupy?” (R. Levins, pers. comm., 2013). This initial plan included the authors coming together later for a study of continental biogeography, although this was never realized (R. Levins, pers. comm., 2013). Current thinking in metapopulation ecology does fit the Core ITB perspective perfectly once changes in scale and geography are incorporated (Hanski, 2010). Core IBT becomes a metapopulation model when one excludes the mainland with its permanent source populations of each species and considers migration among multiple islands (e.g., Mouquet and Loreau, 2002). Although Levins’ (1969, 1970) original model focussed on a single species, and “islands” (habitat patches) that did not differ in size or accessibility, numerous later developments have relaxed these simplifying assumptions (Hanski, 2001, 2010). Furthermore, it is clear that much heritage of both IBT and metapopulation theory has percolated into today’s study of spatial ecology from metacommunities (Leibold et al., 2004; Leibold and Miller, 2004; Logue et al., 2011; Massol et al., 2011) to metaecosystems (Loreau et al., 2003; Gravel et al., 2011; Massol et al., 2011; Leibold and Chase, 2017).

Neutral biodiversity theory (Bell, 2001; Hubbell, 2001) is perhaps the most striking example of an unexpected legacy of IBT. MacArthur and Wilson apparently did not intend for IBT to be thought of as “neutral” at the species level (that is, species treated as ecologically equivalent). The concave functional forms for immigration and extinction rates in Core IBT were partially motivated by potential ecological differences between species (differences in propensity for immigration and extinction; MacArthur and Wilson, 1963; for further discussion see Gilpin and Armstrong, 1981; Schoener, 2010). From a strictly technical perspective, however, species in the classic IBT model are not labeled with their ecological identities. Rather, they are all treated as identical, and the model is thus neutral at the species level regardless of the ideas that motivated it.

The better-known form of neutral theory is one in which individuals (not species) are ecologically equivalent (Hubbell, 1979, 1997), and even the earliest work on such models (Caswell, 1976) notes the similarities with IBT. Later development of “The Unified Neutral Theory of Biodiversity and Biogeography” (Hubbell, 2001) caused a wave of interest in neutral models and further added to the legacy of MacArthur and Wilson as an inspiration for them. In particular, the unified neutral theory incorporates an explicit distinction between the local community and metacommunity, with both maintained at dynamic equilibria. Individual-based neutral theory has since accurately predicted a range of ecological data both in mainstream ecology and in the more specific domain of island biogeography (Bell, 2001; Chave, 2004; Alonso et al., 2006). Although neutral theory is also faced with contrary data (e.g., Ricklefs, 2003, 2006; McGill et al., 2006), it is widely viewed as a useful model to compare with empirical data, highlighting key roles for dispersal limitation, speciation, and ecological drift (Jabot and Chave, 2011; Rosindell et al., 2011, 2012).

While the influence of IBT in ecology is predominantly linked to Core IBT, it is important to note that the legacy also extends to other elements of the 1967 monograph. For example, the penultimate section predicts evolutionary changes following island colonization. MacArthur and Wilson (1967) reasoned that, upon first arriving on an island, a species’ population density is much lower relative to the carrying capacity of the environment than it was at its mainland source. They argued that selection on such newly-arriving immigrants should initially favor adaptations that produce high rates of population growth, even if resources are used inefficiently. They envisaged a contrasting situation for species in the mainland source for which population density is already at the environmental limit; in such source populations, selection should favor the ability to survive and reproduce with limited resources (i.e., efficient resource use). Borrowing notation from standard population models, they coined the terms *r*-selection and *K*-selection for these alternative regimes, respectively. They also argued that once a colonist attains its maximum population size on an island, it will tend to experience a switch back toward a *K*-selection regime (and indeed one that is stronger than on the mainland, due to a temporally more stable climate). MacArthur and Wilson’s (1967) ideas were further developed by Pianka (1970) to make explicit predictions for how individual life-history traits would evolve in response to *r*- and *K*-selection, forming the basis of what became known as life-history strategies. However, the *r*- and *K*-selection paradigm has since been criticized on numerous grounds, in particular that it has been applied in the absence of data on population dynamics, oversimplifies the process of natural selection, and is unable to make precise predictions about phenotypic change (see Reznick et al., 2002 for a review, and more recent related paradigms). Despite such shortcomings, the *r*- and *K*-selection paradigm has been useful in defining fitness under

density-dependent population regulation (Roff, 1992), and retains considerable popularity (e.g., Saether et al., 2016). Furthermore, consistent with the low species diversity of small and remote islands predicted by Core IBT, such islands provide particularly striking examples of rapid change in selection gradients following the arrival of new immigrants (e.g., Losos et al., 2004, 2006).

IBT is a major component of the foundation of modern ecology. Even though our working group included participants with a range of profiles, including island evolutionary biologists and ecological theoreticians, the number of important links with other ecological theories and schools of thought took many of us by surprise. From an ecological perspective, IBT has left a legacy that has (i) forced ecologists to connect local processes to regional patterns and (ii) enabled theoretical ecologists to propose simple models that capture a significant portion of ecological complexity on a biogeographic scale.

Abstract

Islands and atolls are on the forefront of climate change, with sea level rise having some of the most immediate and profound impacts to the people and their surrounding environment. Since the industrial era of the late 1800s and particularly following World War II, global prosperity and the energy demands to meet growing economies has resulted in increasing emissions and accumulation of greenhouse gasses in our atmosphere. Greenhouse gasses such as CO₂ from the combustion of fossil fuels have allowed for the retention of radiative heat, which has resulted in increasing atmosphere and ocean temperatures above pre-industrial levels. Increasing temperatures, especially in the last 20 years, have resulted in the loss of ice from large ice sheets and receding glaciers, and an increase in the intensity of tropical cyclones with high storm surge events. The combined loss of ice and thermal expansion of sea water causing sea levels to rise, and storm surge events that flood and erode islands and atolls, have resulted in the first documentation of islands lost to sea level rise. The loss of islands and atolls constitute socioeconomic, cultural and environmental impacts that are a consequence of global economies, which cannot be mitigated at the local level alone. Global efforts have been central to establishing predictions and recommendations for reducing greenhouse gas emissions to levels that would slow the progression of climate change and allow time for economies to adjust to cleaner energy sources. Shifts in energy sources and increasing efficiencies however will require an unprecedented global-scale shift in the way we live. Central to this will be shifts to more renewable energy sources and efficiencies such as wind and solar power, both of which require technical advances to be applied more widely around the world.

Introduction

We have all seen how global climate change influences the way we live and think about our planet. For most, this has been in our experiencing unseasonal weather patterns, and in our changing attitudes and lifestyles to reduce our footprint on the environment. For those living on islands and atolls, the implications of climate change have a much more direct and impending result. Increasing emissions of greenhouse gasses in the last century have resulted in increasing atmospheric and ocean temperatures, resulting in more extreme weather events including tropical cyclones and sea level rise that together threaten the existence of these communities and the surrounding ecosystems. Islands and atolls are unique in many ways, with their relative isolation having endemic species and biodiversity, which are often central to the livelihood and culture of the people that live there. This isolation also imposes a reduced capacity for communities and organisms to adapt, especially in a time of rapid climate change and sea level rise. In fact, islands and atolls are on the forefront of this change, with the highest levels of biodiversity loss and first extinction of a species of mammal (Bramble Cay melomys, *Melomys rubicola*) due to climate change, and the displacement of whole communities and cultures from island systems, as seen in Micronesia and the Solomon Islands of the Western Pacific.

The concept of human-induced climate change was seeded in 19th century geological and paleoclimate sciences and by mathematicians and physicists, where it was first recognized that the earth's climate in the past was not static, and that the emission of hydrocarbons (major greenhouse gasses) into the atmosphere would eventually cause warming. Despite this early discovery, it was only until the 1970s when scientists and the public began to be concerned, with a general consensus by the global scientific community in the late 1980s with the establishment of the first Intergovernmental Panel on Climate Change (IPCC; <https://www.ipcc.ch/>; accessed 13Aug 2019). What would seem to be a slow progression of science leading up to recognizing climate change was and still is a result of the complexity of our earth and climate, and the progression of science and technology to monitor it with. Since the 1990s, advances in satellite imagery, ground-based measurements and computers have allowed for a near-continuous monitoring earth's temperature, ice coverage, and changing weather patterns that can influence sea level rise.

This article dives into the causes and effects of climate change and sea level rise, and how this is impacting islands and atolls now and into the future. This article will present and discuss the physical dynamics of climate change and sea level rise, and how sea level rise is impacting island communities and the surrounding natural ecosystems from which they depend on for culture, subsistence

and economic prosperity. Finally, we will discuss what is being done to reverse climate change, from international agreements to reduce emissions to taking steps to reduce other sources contributing to global warming.

Climate Change and Sea Level Rise

Climate Change

The causes of climate change is a story of global economic prosperity, especially in the last 70 years following World War 2 with increasing energy demands feeding a growing global economy. Increased emissions of greenhouse gases has predominantly come from electricity generation, agriculture, industry and transportation, much of which comes in the form of carbon dioxide (CO_2), and to a lesser extent methane and nitrous oxide (agriculture and forest practices), and fluorinated gasses (industrial processes, refrigeration). Greenhouse gasses in the atmosphere cause warming by trapping radiant heat from the earth that would otherwise be lost to space, with the continued buildup of greenhouse gasses over time causing, on average, a continued warming of the earth's atmosphere and warming of oceans that absorb this heat (Fig. 1).

Over the last century, total CO_2 emissions have risen by over an order of magnitude, with an estimated 68% increase over the last 20 years alone (Fig. 2). Over this same time span, global average temperature anomalies (temperatures above the global average) have increased by nearly 60%, with ocean temperatures responding with an average increase in the anomaly of 57% (Fig. 3). To put this into perspective, from the recording of temperature records since the 1880s and backward over 2000 years of reconstructed temperature records, the earth has never been warmer than the last 20 years. With continued emissions of greenhouse gasses at the current rate and continued ocean warming, current knowledge and application of climate models projects regions such as the Arctic to be completely free of ice by 2060 (2014 National Climate Assessment, <https://nca2014.globalchange.gov/report>). This rapid increase has been attributed in-part to another dynamic of global warming, in which the loss of sea and land ice has removed the reflective properties of the surface, with the sun's heat being more absorbed by darker, less reflective surfaces of the oceans and land. This is causing a type of positive feedback of loss of ice due to warming, which causes more absorbance of the sun's rays and further warming.

Sea Level Rise

The link between atmospheric and ocean warming to sea level rise first brings to mind the contribution of water from the loss of large ice sheets in polar regions, Greenland, and receding glaciers, adding volume to oceans. Indeed, these freshwater pools constitute upwards of 68% of earth's surface freshwater, which if completely melted would cause sea level to rise by 70 m (230 ft), virtually inundating most low lying atolls and islands (citation?). Another significant but less known contributor to sea level rise is through the thermal expansion of seawater, which is a function of the water's density and temperature. As global atmospheric temperatures rise and heat is absorbed by the oceans, sea temperatures rise and seawater expands. To what extent thermal expansion contributes to sea level rise however is much more complex and is debated, in part because of the dynamics of ocean mixing across

Fig. 1 Schematic of how greenhouse gasses effect global warming, with natural conditions (left) having a greater proportion of solar radiation escaping to space relative to the scenario of higher levels of greenhouse gasses (right) that insulate re-radiated heat from escaping the atmosphere (<https://www.c2es.org/content/climate-basics-for-kids/>).

the globe and differences in pressure and temperature with depth, and our inability to measure this complexity. It is therefore understandable that there have been some differences in results from researchers trying to measure and predict sea level rise contributions from thermal expansion and ice melt. Limits in our use of land and satellite-based measures and how to interpret the data are central to these differences, but the main message from nearly all studies is that both ice loss and thermal expansion are significant contributors to the dynamics of sea level rise. Deciphering this will require further advancements in the tools we use to measure and model ocean systems.

With sea level rise occurring at an estimated 3 mm/year (Fig. 4), it has been predicted that mean sea levels will start to impact islands and coastal zones by the mid-century. However, the first signs of sea level rise to islands and atolls are being observed now through tropical cyclones (hurricanes and typhoons), which can push water toward the shore by the force of the winds moving cyclonically around the storm, a phenomenon called “storm surge.” There can also be an added increase in water height due to the low pressure associated with storm surge, but this is minimal relative to the piling of water to land from winds. Islands and atolls already experiencing elevated sea levels are thus immediately threatened by storm surge and waves, which in some cases can be over 20 ft above local average sea heights. In 2005, within the Gulf of Mexico the category-5 hurricane Katrina carried a storm surge of between 24 and 28 ft, covering 90 miles of the coastline consisting of islands and low-elevation coastal areas. The impacts of storm surge cover immediate flooding, erosion and loss of lands. Somewhat unique to islands and atolls and particularly from porous coral lands, the intrusion of seawater from storm surge can contaminate groundwater, making the island uninhabitable to humans and wildlife.

Regional Effects of Sea Level Rise

Sea level rise is a global issue, but the distribution and impact of sea level rise is not evenly distributed across oceans due to differences in ocean-atmospheric interactions, and the elevation and geological makeup of the land. The greatest increases in sea level rise and impacts to islands and atolls have been first seen in the western tropical Pacific and Indo-Pacific regions which contain most of the world’s low-lying islands and atolls (Fig. 5). The western Pacific is observed to have some of the greatest increases in sea level rise due to El Niño-related piling of water toward the western Pacific from sustained trade winds. The combination of low lying islands and atolls, many of which are no higher than 4 m and their geological makeup of coral has made this region the most prone to erosion and inundation (Figs. 6 and 7). As a result, the south Pacific and Indo-Pacific islands have been the sentinels of sea level rise, expressing the first scientific confirmation of islands lost due to rising seas and erosion in the Solomon Islands (Micronesia). Under the IPCC Special Report on Emission Scenarios, one of the scenarios predicted an annual increase of 3–4 mm-year with an increase of between 0.22 and 0.44 m in the 2090s to 1990 levels, which would cause further erosion and inundation of the world’s most vulnerable region to sea level rise. As we will see later in this article, this has led to some of the first occurrence of island communities to plan for eventual loss of their islands.

Ecological Impacts

Islands and atolls are of the most ecologically vulnerable to sea level rise due to their susceptibility to erosion and inundation, and their relative isolation of unique habitats, species, and communities. We have all heard of the large flightless Dodo bird (*Raphus*

Global Land Temperature Anomalies, January-December

Global Ocean Temperature Anomalies, January-December

Fig. 3 Annual global land (top) and ocean (bottom) temperature anomalies from 1880 to 2019 (<https://www.ncdc.noaa.gov/cag/global/time-series/globe/ocean/1/1/1999-2019>).

cucullatus) of the islands east of Madagascar in the Indian Ocean, a species that went extinct due to overharvest and the introduction of invasive species (Citation). Although climate change didn't play a role in its demise, the Dodo is probably the most iconic animal representative of the vulnerability of island species to extinction. In fact, of the 724 recorded animal extinctions in the last 400 years, about half were island species (Citation). As islands and atolls are the most susceptible to sea level rise, they are the first indicators of measuring biodiversity loss, both the species that reside on land and those that reside in nearshore waters.

Marine aquatic species that rely on islands and atolls predominantly rely on habitats within shallow reef flats (within atolls) and coral reefs. Corals are bioengineers of their environment, growing hard substrate around islands that act as a barrier to erosion from sea level rise and storm events, and providing a rich diversity of habitats from which species have evolved to rely on for food and cover. In a recent study (Perry et al., 2018), researchers measured the vertical growth rate of corals to assess the threat of sea level rise to coral reefs, and they found that coral growth will not be able to keep up with current rates of increasing sea levels. Moreover, corresponding increasing ocean temperatures may further impede growth due to heat-related stress and coral bleaching. The implications of this include the potential loss of coral reefs and their rich biological communities, and the increase in loss of land due to exposure to waves and erosion. The effects to more shallow water reef and sand flat communities that are characteristic within atolls

Fig. 6 Abaiang Atoll, Republic of Kiribati, showing part of the atoll's lagoon and low-lying island ring and the susceptibility to erosion and sea level rise (<http://simondonner.blogspot.com/2013/05/kiribatis-battle-against-sea-level-rise.html>).

Fig. 7 Sea level rise in the Solomon Islands. The combination of sea level rise and increasing storm surge has made communities and ecosystems highly vulnerable to erosion and inundation (<https://www.newstalk.com/news/as-sea-levels-rise-in-the-pacific-five-of-the-solomon-islands-have-disappeared-598805>).

are not well known, due in part to these habitats being less studied. But the dependence of inner-atoll species on these shallow water habitats undoubtedly place them under direct threat of sea level rise because of the very nature of shallow waters being vulnerable to erosion and the eventual loss of low-lying atolls.

Of all species related to islands and atolls, the most susceptible to extinction from sea level rise spend at least part of their life on land. Islands are home to 20% of the world's bird, plant and reptile species, a number of which are endemic and not found anywhere else in the world. Many species of birds use islands as rest areas, foraging grounds and nesting and rearing, all of which are critical to their long-term survival. Sea turtles such as the green (*Chelonia mydas*) and leatherback (*Dermochelys coriacea*), although aquatic, rely on sandy beach habitats for nesting that are directly threatened by storm surge and increasing sea levels. Terrestrial plants and animals such as endemic invertebrates (insects, snails, and crabs), birds and mammals are constrained to their limited land habitats, the loss of which can account for significant impacts to the genetic integrity at the population and species level. As islands disappear, the loss of extant populations and their genetic diversity can reduce connectivity between populations on other islands, reducing their resiliency to persist in a changing climate. Ultimately, the loss of species can undermine whole ecosystems and the very web of life that island nations depend upon for subsistence and economic prosperity.

Socioeconomic and Cultural Impacts

As islands and atolls are on the forefront of climate change and sea level rise, so are the socioeconomic and cultural impacts that are embedded within communities and whole island nations. Islands and atolls are commonly isolated, with communities having a high proportion of their livelihood based on subsistence living and economies that are tied to nearshore resources and tourism. Most of the urban and rural communities of the western tropical Pacific islands, as well as other island systems around the world rely on healthy nearshore ecosystems as a major (>50%) source of food-protein from fish and invertebrates, the diminishing of which would undermine food security and economic opportunities in fisheries. In terms of tourism, the loss of coral reefs and beach habitats would undermine diving/snorkeling and sport fishing which are core to destination tourism in island economies. For example, the island nations of Fiji, Vanuatu, Kiribati which are of the most threatened to sea level rise receive between 20% and 40% contributions to their total economies (citation?). Aside from the loss of healthy ecosystems for subsistence and economic prosperity, the loss of potable freshwater from saltwater intrusion and climate-driven droughts, and increasing intensity of storm events have also been realized as major threats to the future of island and atoll communities.

One of the more eye-opening responses to early stage sea level rise to island and atoll communities has been the recent consideration of having open-access migration of people from threatened island and atoll nations (e.g., Tuvalu and Kiribati) to other countries such as Australia and New Zealand. This "climate refugee" scheme (is there a citation for this?) has not been to empty island nations but to preemptively address a potential rush to leave islands to other regions in the future, and to make these nations more sustainable, economically and environmentally given projections in population rise. The potential loss of islands and atolls to rising sea levels however leave few other options for life on the islands. Some have proposed alternative measures such as building walls and barriers to protect from erosion and intrusion, which have their own set of environmental impacts to reefs and species that need specific nearshore habitats, such as sea turtles, shore birds, fish, and invertebrates. For example, in Indonesia, there is a plan to build a giant sea wall, build a water reservoir and reclaim land in order to save the world's fastest sinking city (https://en.wikipedia.org/wiki/Giant_Sea_Wall_Jakarta, accessed 13 Aug 2019). The ultimate loss of islands or inhabitability due to sea water intrusion leave

no other options other than moving people off island. In this case the migration of people to distant lands would constitute not only an economic loss but more critically the loss of heritage and cultures that have evolved with the islands for thousands of years.

Mitigation

The causes of climate change and sea level rise has had a disproportionate effect on island communities due to the sources coming from more developed and populated regions of the world. As a result, addressing the progression of climate change will require a global effort to make unprecedented changes in the way we live. As the center for scientific knowledge, synthesis, and guidance on climate change, the IPCC has used global temperatures as reference points to preindustrial era levels, with our current state being approximately 1°C (XF) above values from the mid-1800s. From this, the IPCC has set future gas emissions and carbon budgets to estimate how much greenhouse gas levels would need to be reduced to reach threshold levels of between 1.5 °C and 2 °C. Based on their 2014 report, in order to avoid global temperatures to exceed the 2 °C threshold, greenhouse gas emissions in 2050 will have to be 40–70% lower than what they were in 2010 (IPCC, 2014). This reduction would not remove effects of warming and sea level rise, but would lessen future impacts and allow time to adjust economies and society to alternative energy sources. This reduction will require unprecedented changes in the way we live, encompassing shifts toward nonhydrocarbon energy sources, and major shifts in nearly every aspect of society including industry, housing, and transportation.

As a global issue, nations are coming together to agree on policies to reduce greenhouse gas emissions based on the 1.5 °C and 2 °C threshold levels set by the IPCC. Central to this has been the Paris Agreement (<https://unfccc.int/process-and-meetings/the-paris-agreement/the-paris-agreement>, accessed 13 Aug 2019), which was signed in 2016 to bring nations together to address greenhouse gas emissions mitigation, adaptation, and finance. Proposed measures of mitigation have pushed for nations' to shift to cleaner alternative energy sources and to increase efficiencies. However, of the 31 main economies on the Paris Agreement, to date only 7 have at least met the ≤ 2 °C threshold, with 9 at < 3 °C, and 15 at < 4 – $4 +$ °C. China and the United States which comprise 40% of the world's emissions are currently at the < 4 and $4 +$ °C threshold, respectively. The primary shifts in energy to work toward lowering emissions and ultimately the 1.5–2 °C level have been wind, solar and hydropower (and somewhat controversial use of nuclear power). Wind and solar power can be highly effective however they are limited by areas/regions with sustained conditions to provide a constant source of energy. Both of these options also require the capacity to store energy, and future technology in battery capacity is critical to making wind and solar power more amenable to regions across the world. Hydropower can be generated a number of ways, either through dams or tidal and wave generation. Of these, dams can have a profound environmental impact on river and riparian systems, altering habitats and restricting migration of fish and other organisms that rely on unimpeded waterways to survive.

At the local level of islands and atolls, the options for adapting to climate change and sea level rise are few. Proposals for the placement of barriers to reduce erosion and walls to hold back flooding are fraught with environmental impacts, such as the destruction of essential habitat for many species that use the nearshore and shoreline habitats around islands. Other proposals to raise land and building homes on stilts have also been considered, the results of which would only be a short-term fix to a problem that will continue into the future if emissions are not substantially reduced. For all of the above options, the economic cost of building barriers or elevating lands and structures also make it nearly cost-prohibitive. As discussed earlier, with the progression of sea level rise the only option will be the migration of populations to higher lands.

Abstract

The Island archipelagos of the Arctic Ocean support the most extreme examples of Arctic-adapted plant and animal communities. Compared with much of the planet, they have seen relatively little human disturbance. Their current faunas and floras have been strongly influenced by the degree of isolation of the different island groups and by Pleistocene glaciations and post-Pleistocene sea-level changes. Faunal interchange with adjacent continents has been modified by the annual connection via winter sea-ice. Current trends towards warmer temperatures and shorter sea-ice seasons in the Arctic may eventually result in the loss of seasonal ice-bridges, isolating some archipelagos and preventing colonization by southern faunal elements. Understanding and protecting these islands is the key to preserving the current remnants of the Pleistocene fauna and flora.

Introduction

The Arctic Ocean, along with the adjacent Kara, Barents, Laptev, East Siberian, Chukchi and Beaufort seas, and circumscribed by the northern extremities of Greenland and the Eurasian and North America continents, contains several important island groups. The largest of these are Svalbard (Norway), Novaya Zemlya, Franz Josef Land (*Zemlya Frantsa-Iosifa*), Severnaya Zemlya, the New Siberian Islands (*Novosibirskiye Ostrova*), and the comparatively isolated Wrangel Island, along with its small companion, Herald Island, all in Russia, and the Canadian Arctic Archipelago (Fig. 1). The Canadian islands include some very large ones situated close to the North American mainland (e.g., Baffin, Victoria, Banks islands) which are ecologically indistinguishable from the adjacent mainland. Consequently, for this review, I deal only with the Queen Elizabeth Islands to the north of the Parry Channel—Viscount Melville Sound—M'Clure Strait waterway at about 74°N (Fig. 2). These islands are more comparable, ecologically, to the other Arctic Ocean archipelagos than those farther south. For some purposes, I will discuss the Palearctic islands in two groups: (1) the islands of the Barents and Kara seas (Fig. 3), which experienced only brief and limited connections to continental Eurasia during the last glaciation and (2) the East Siberian Sea islands (Fig. 4), which for most of the last glaciation stood within a broad coastal plain extending hundreds of kilometers north of the current coast of Siberia.

Pleistocene and Holocene Histories

All of the islands under consideration were strongly affected by events during the last ice age (Pleistocene) and especially by the last glacial advance (Wisconsinan/Weichselian) and by postglacial (Holocene) events, especially sea-level changes. Many of the islands

Fig. 1 The Arctic Ocean and the surrounding archipelagos and islands (Google Earth Pro, 2018).

Fig. 2 Islands of the Canadian Arctic Archipelago, north of the Parry Channel—Viscount Melville Sound—M'Clure Strait waterway (Google Earth Pro, 2018).

were entirely, or almost entirely covered by ice at the peak of glacial periods and consequently their terrestrial ecosystems tend to be very young, dating from the period of Wisconsinan deglaciation ~10,000 years ago. The only exceptions were Wrangel Island and parts of the New Siberian Islands and the northwesternmost of Canadian high Arctic islands, none of which was glaciated. As well, the reduced sea-levels of the glacial period exposed large areas of additional land around all of the archipelagos, especially Severnaya Zemlya and the islands of the East Siberian Sea, all of which had long-lasting land connections to the mainland of Asia during Pleistocene sea-level minima (Tolmachev, 1970; Formana et al., 2004; Jakobsson et al., 2012). These low-lying areas would have supported additional periglacial land which would have been home to a continental fauna and flora, components of which later became marooned after postglacial sea-levels rose (Andreev et al., 2009). Remnants of Pleistocene ice sheets remain on Devon, Ellesmere and Axel Heiberg islands, in Canada, on all the major islands of Svalbard and in Franz Josef Land, Novaya Zemlya and

Fig. 3 Islands of the Barents and Kara seas (Google Earth Pro, 2018).

Fig. 4 Islands of the East Siberian Sea (Google Earth Pro, 2018).

Severnaya Zemlya in Russia. Isostatic uplift, following the decay of major ice sheets, has affected most of the islands previously glaciated, leading to the creation of extensive raised beaches (Fig. 5).

Terrestrial Ecosystems

Flora

The vegetation of all the Arctic Ocean islands consists predominantly of graminoid and prostrate dwarf shrub tundra (G1 and G2, CAV Team, 2003) and lichen and moss-dominated cryptogam barrens (B1, B2). All these communities are characterized by plants of very short stature. The archipelagos fall within seven floristic provinces (clockwise from Wrangel I.): West Chukotka (Wrangel I.), Yana-Kolyma (E Siberian Is.), Taimyr (Severnaya Zemlya), Polar Ural (Novaya Zemlya), Svalbard-Franz Josef, Ellesmere-N Greenland (Ellesmere and Axel Heiberg islands and eastern Devon I.), Central Canadian Arctic (western Queen Elizabeth Is.). Provinces are defined on the basis of taxonomic affinities resulting from post-Pleistocene colonization processes, but the genera involved show much overlap (Daniëls et al., 2013). The most diverse and widespread families are Caryophyllaceae, Cruciferae, Cyperaceae, and Saxifragaceae and the most diverse genera *Carex*, *Draba*, and *Saxifraga*. There is a relatively low incidence of

Fig. 5 Raised beach deposits behind shorelines near Resolute Bay, Nunavut, Canada (Google Earth Pro, 2018).

endemism, presumably because of the relatively short time since deglaciation. Significantly, highest endemism is found at the unglaciated Wrangel Island, where 35 vascular plants endemic to the Arctic are present (33% of all Arctic endemics; Daniëls *et al.*, 2013). Wrangel Island also has a greater total diversity of vascular plants (315 species) than either Ellesmere Island, in Canada (199 species), or Svalbard (211 species), both considerably larger (Cf. Petrovskii and Yurtsev, 1970).

Vegetation throughout the Arctic Ocean archipelagos is very sparse, and few plants grow above 200 m altitude, apart from prostrate mosses and lichens. Above ground plant biomass is predominantly less than 50 g m^{-2} (CAV Team, 2003). Soils throughout are underlain by permafrost, impeding drainage and encouraging the creation of tundra polygons and bogs (Fig. 6), but as most precipitation falls as snow, there are few permanent watercourses. Many of the islands experience little rainfall and are regarded as polar deserts. Vegetation is frequently restricted to seasonal drainage channels (Fig. 7). The main factors controlling plant growth and the consequent vegetation communities in the high Arctic are summarized by Aiken *et al.* (2018):

- "Climate, which imposes a major temperature-based zonation, modified by local climates or microclimates;
- Drainage, which controls the summer water regime and has some effect on frost action;
- Nutrients, that are in limited supply in most arctic soils;
- Local soil type, which, along with climate and drainage, influences soil stability and fertility;
- Snow cover, which controls the duration of the growing season."

Fig. 6 Ice-wedge polygons on lowland tundra, Wrangel Island (Google Earth Pro, 2018).

Fig. 7 Braided drainage with vegetation concentrated along drainage channels, Khuzny Island, Novaya Zemlya (Google Earth Pro, 2018).

Despite the generally very low productivity of terrestrial biomes on the archipelagos, small areas exist where local conditions of moisture and soil types combine to create much lushier areas, sometimes termed “high Arctic oases” (Edlund and Alt, 1989). Examples in the Canadian islands include Polar Bear Pass on Bathurst Island (Sheard and Geale, 1983; Fig. 8), Lake Hazen on northern Ellesmere Island (Fig. 9), and Truelove Lowland, on Devon Island (Bliss, 1977; Fig. 10, Cf. Fig. 11) and. These areas typically support a much higher density of grazing mammals, hence also of wolves, than areas of lower productivity.

Oceanography

All the island archipelagos fall within Arctic waters, but the southeastern coasts of the Canadian islands and the west coast of Svalbard are affected by milder waters originating from the North Atlantic (Tang et al., 2004; Wassmann et al., 2006). To a small extent this is also true of Wrangel Island, where a plume of warm water, originating from the Bering Sea, moves westwards towards the east coast (Ahlén and Garrison, 1984). The waters surrounding all archipelagos are currently 100% covered by sea ice in winter

Fig. 8 Polar Bear Pass on Bathurst Island, a “high Arctic oasis” with a concentration of ungulates, loons, shorebirds, jaegers and snowy owls (Nettleship and Smith, 1975).

Fig. 9 Lake Hazen, a glacier-fed lake on northern Ellesmere Island (Google Earth Pro, 2018).

Fig. 10 Truelove lowlands and lowlands near Cape Sparbo, two “high Arctic oases” on the northeast coast of Devon Island (Cf. Fig. 11; Google Earth Pro, 2018).

but break up along the west coast of Svalbard occurs in May and in June in Baffin Bay and Lancaster Sound, south and east of Devon Island, and in the Kara Strait, south of Novaya Zemlya. Break-up in waters surrounding the other island groups occurs in July or later and in some years sea ice remains year-round adjacent to parts of Franz Josef and Severnaya Zemlya, giving these archipelagos very cool summers.

Terrestrial Vertebrates

The terrestrial vertebrate fauna of the various archipelagos largely reflects their isolation from continental landmasses. Both Wrangel Island and the New Siberian Islands were connected to the Asian mainland during periods of low sea levels which persisted into the postglacial period, so that they supported a diverse fauna including woolly mammoth, wild horses and musk oxen (Boeskorov,

Fig. 11 North-central Devon Island—dry upland area with low moisture and little vegetation (Google Earth Pro, 2018).

2004). The birds and mammals of the Canadian islands, with a maximum water barrier of 48 km separating them from the North American mainland (Gaston et al., 2012), are similar to those of mainland North American Arctic ecosystems, while those of the other archipelagos vary in their diversity, with Svalbard and Franz Josef Land, the most isolated groups, being the most depauperate. Svalbard supports only 15 species of nonmarine birds, compared to 36 species in the Canadian islands (Ganter and Gaston, 2013). Moreover, there are no wholly freshwater fishes in Svalbard (anadromous Arctic Char *Salvelinus* sp. is present).

Mammals

Arctic fox and polar bear occur on all the Arctic archipelagos. Traveling and living on the sea-ice, as they do in winter, they are capable of reaching all land masses in the Arctic ocean. Otherwise, all of the archipelagos have supported at least one species of terrestrial mammal (Fig. 12), but the most isolated (Svalbard, Franz Josef) support only reindeer/caribou *Rangifer tarandus* (reindeer

Fig. 12 Distribution of terrestrial mammals on Arctic Ocean archipelagos (data from Gaston et al., 2012).

became extinct on Franz Josef more than a millennium ago (Zale et al., 1994). Within the Canadian Arctic, caribou routinely move across sea ice over distances of up to at least 84 km (Miller et al., 2005). This suggests that herds on Novaya Zemlya, Severnaya Zemlya and the New Siberian Islands should be capable of interchange with Siberian mainland populations. Wrangel Island (140 km from the Siberian mainland), Franz Josef (367 km from Novaya Zemlya) and Svalbard (220 km from Franz Josef, and 640 km from mainland Norway) may be outside the normal over-ice dispersal range for caribou. Populations on those archipelagos, only one of which persisted into historic times, may have colonized those islands during the Pleistocene when lower sea-levels would have reduced over-ice distances. The current isolation of Svalbard caribou is emphasized by their low genetic diversity (Cronin et al., 2006).

Diversity of mammals is greatest on the islands of the Canadian archipelago, where all the “Arctic specialists” can be found. It is the only group of islands supporting Musk Ox *Ovibos moschatus* and the Arctic hare *Lepus arcticus* is found on most islands, whereas its congener in Eurasia, the mountain hare *Lepus timidus* only reaches the southernmost islands of Severnaya Zemlya, Novaya Zemlya and New Siberian Islands. Lemmings, *Dicrostonyx* and *Lemmus* spp., are found on all the larger islands in the Canadian Archipelago, on Novaya Zemlya, Severnaya Zemlya, the New Siberian Islands and Wrangel Island, but not on Franz Josef or Svalbard, presumably because of their isolation (Fig. 5).

Among carnivores, wolf *Canis lupus* is found on most of larger Canadian islands, except the westernmost, where caribou are also rare, and on all the Russian archipelagos except Franz Josef, although only an occasional visitor on Severnaya Zemlya (Gaston et al., 2012). The ermine *Mustela erminea* occurs on all the larger islands where lemmings occur, while the wolverine *Gulo gulo*, although very sparse, has been recorded on several of the Canadian islands, but is absent from the Palearctic archipelagos apart from Wrangel Island (Fig. 12).

Birds

Being able to fly allows birds to readily colonize distant islands so that their distribution is less affected by the periodic availability of land connections. Many high Arctic species have circumpolar distributions, (e.g., red-throated loon *Gavia stellata*, willow and rock ptarmigan *Lagopus lagopus*, *L. mutus*, gyrfalcon *Falco rusticolus*, snow bunting *Plectrophenax nivalis*, Lapland longspur *Calcarius lapponicus*). However, geese and shorebirds tend to be confined either to the Nearctic (e.g., Ross's goose *Anser rossii*, semipalmated, white-rumped, western and Baird's sandpipers *Calidris pusilla*, *C. fuscicollis*, *C. mauri*, *C. bairdii*, or the Palearctic (e.g., pink footed, bean and barnacle geese *Anser brachyrhynchus*, *A. fabalis*, *Branta leucopsis*, dotterel *Charadrius morinellus*), little and red-necked stints *Calidris minuta*, *C. ruficollis*, curlew sandpiper *C. ferruginea*).

In contrast with terrestrial mammals, diversity of waterfowl and seabirds among the Arctic Ocean islands, is highest on Svalbard, the most remote archipelago (Figs. 13 and 14), perhaps because of lack of terrestrial predators and competitors. The reverse is true of rodent-eating birds because most Arctic raptors depend on lemmings to provision their young and consequently most are absent from Svalbard and Franz Josef (Fig. 15). Shorebirds diversity is fairly similar among archipelagos (Fig. 16), with the exception of

Fig. 13 Distribution of breeding waterfowl among Arctic Ocean archipelagos. Data from Portenko (1972), Cramp (1977, 1982, 1983, 1985), De Korte et al. (1995), and Ganter and Gaston (2013).

Franz Josef, where only a single species breeds (purple sandpiper *Calidris maritima*). Shorebird diversity may relate principally to the extent of suitable habitat—for most species lowland wet tundra with sedge meadows—rather than to isolation.

Marine Ecosystems

Mammals

The islands of the Arctic ocean play an important role in marine ecosystems by providing breeding and hauling out opportunities for marine birds and mammals. Among mammals, the Arctic Ocean islands are particularly significant for polar bears *Ursus maritimus* and walrus *Odobenus rosmarus* which are found on all the archipelagos, although walrus are absent from the western and northern Queen Elizabeth Islands.

Walrus haul out on sea-ice when it is present, but once the seasonal ice has gone, they haul out on shore in dense aggregations which can number thousands of animals. They persist in areas of extensive winter ice cover by exploiting polynyas—areas of water kept open by strong currents and upwellings, but some populations are migratory, particularly the Pacific subspecies (*O. r. divergens*), which commutes between winter in the Bering Sea and summer in the Arctic Ocean, when large numbers occur at Wrangel Island (Aug–Oct; Fay, 1982). Despite this very large biomass of marine animals coming on land periodically, walrus have little impact on terrestrial ecosystems. Their droppings are deposited very close to the high-water mark and are mostly washed into the sea. They may provide prey for polar bears and carcasses, either killed by bears or other causes, may provide food for scavengers, such as ravens and gulls.

In contrast, polar bears may have significant impacts on terrestrial ecosystems. While ashore in summer, after the retreat of sea ice, they feed on grasses and forbs, as well as on birds' eggs and nestlings, on lemmings and caribou and on freshwater fishes. They frequently congregate in the vicinity of walrus haul-outs and kill smaller animals, especially dependent pups. Females frequently dig maternity dens on shore, in persistent snow drifts, usually within a few kilometers of the coast (Stirling, 1988).

The existence of the Arctic Ocean islands extends enormously the area of the Arctic Ocean accessible to both walrus and polar bears. The islands give access to haul-out and denning sites and, with their indented coastlines, provide excellent habitat for ringed seals *Pusa hispida*, the primary prey of the polar bear, as well as creating the type of narrow straits through which tidal currents maintain year-round polynya necessary for overwintering walrus.

Seabirds

Some species of seabird breed in dense colonies which not only provide opportunities for land-based predators, but also affect the local terrestrial ecosystems by importing large quantities of marine nutrients (Fig. 17) into the terrestrial environment (Klimowicz et al., 1997; Jónsdóttir, 2005; Zwolicki et al., 2013). The most common species breeding on the Arctic Ocean islands are the northern fulmar *Fulmarus glacialis*, thick-billed murre *Uria lomvia*, black-legged kittiwake *Rissa tridactyla*, dovekie *Alle alle*, and black guillemot *Cepphus grylle*. The murre and kittiwake normally breed on very steep coastal cliffs. Consequently, much of their droppings wash into the sea. However, dried feces, along with discarded food remains, are frequently blown up the cliffs by strong winds and are deposited in a zone which may be up to a kilometer wide inland from the cliff edge. Enrichment of the vegetation in this zone is clearly apparent at many colonies (e.g., Gaston and Donaldson, 1996). The effects of dovekie manuring can be more extensive, because their colonies are often situated some kilometers inland and the effects of manuring are found over the intervening area (Zwolicki et al., 2013). Similar effects can be seen on small islands where dense aggregations of common eider *Somateria molissima* breed.

Biogeography

The Arctic Ocean archipelagos share many physical characteristics related to their harsh climates and remoteness and many plants and animals occurring in the high Arctic archipelagos have circumpolar distributions. In the case of less widespread taxa, the flora and fauna of the Eurasian archipelagos are dominated by plants and animals of Palearctic affinities, whereas those of the North American sector include a greater proportion of organisms with Nearctic affinities. This division is more striking when we consider birds than for other organisms, perhaps because most Palearctic migrants winter in Asia or Africa, whereas most Nearctic migrants winter in the Americas. Some birds in the eastern Canadian high Arctic, however, move eastwards in fall to winter in Europe and Africa, migrations which presumably mirror the pathways by which they colonized the high Arctic after the last glaciation.

Human Influence

Human history in the Arctic Ocean islands goes back to mid-Holocene times on the New Siberian Islands, at Wrangel Island and at some (perhaps all) of the Canadian islands (Sutherland, 1980), including Ellesmere (Schledermann, 1978), Axel Heiberg, Devon and Cornwallis islands. However, Svalbard and Franz Josef Land probably were not accessed by people before being discovered by modern Europeans some time after 1000 CE (Chochorowski, 1991). Perhaps because of a general deterioration of climate during

Fig. 17 Freshwater ponds at the base on the Northern Fulmar colony at Cape Vera, Devon Island. The bright green margins show the effects of nutrient enrichment by the Northern Fulmar colony on the cliffs just inland of the ponds. Photo: Mark Mallory.

the last millennium, compared with the earlier Holocene, native people were absent from all of the archipelagos, other than Novaya Zemlya, by the time the islands were discovered by medieval and later whalers and explorers.

In the New Siberian Islands, evidence of Mesolithic hunters has been found on Zhokov Island (77 km²), in the northern part of the archipelago. A site dated at 7900 BP suggests that the hunters killed caribou and polar bears (Pitul'ko, 1993). By that period sea levels were similar to the present day, so these people had the technology to cross substantial water barriers: Zhokov is more than 100 km from Novaya Sibir Island, the easternmost of the larger East Siberian Islands and 38 km from the nearest potential “stepping stone” island.

Discovery of the Arctic archipelagos by Europeans may have begun with contact between Vikings and Inuit on Ellesmere Island, some time after 1200 CE (Schledermann, 1980). Vikings may well have discovered Svalbard, as well, but the discovery is generally attributed to the Dutch explorer Willem Barentsz who saw the islands in 1596. Thereafter the archipelago was used as a base for whaling (mostly Bowhead *Balaena mysticetus*) until stocks were more or less exhausted in the early 18th century (Woodby and Botkin, 1993). Surprisingly, considering the extent of activities on Svalbard, the Franz Josef archipelago was not discovered until the late 19th century, although it is possible that walrus hunters were familiar with it earlier. The Canadian high Arctic group was first sighted by William Baffin, who saw both Devon and Ellesmere islands, searching for the Northwest Passage in 1616. The islands were not seen again by Europeans until the renewal of attempts to find the Northwest Passage in the 19th century. Unlike the other island groups, New Siberian Islands were discovered by land and ice crossing in 1712 by a Cossack company. Herald Island, adjacent to Wrangel Island, was sighted in 1849 but the first people to land were probably the crew of USRC Corwin in 1881 and Severnaya Zemlya was the last archipelago to be discovered, by Russian icebreakers in 1913 (Wikipedia, 2018).

The archipelagos of the Arctic Ocean comprise some of the remotest and most physically challenging places on earth. The combination of high latitude, proximity to the frigid waters of the Arctic Ocean and the presence, in many places, of mountains and remnant ice-caps, combine to make these some of the coldest places with permanent settlements. Recent permanent habitation on the archipelagos, excluding military installations and weather stations, occur on the Canadian islands, on Svalbard and on Yuzhny Island (the southern island of Novaya Zemlya). The population in the Canadian islands comprises two small Inuit communities: Resolute Bay on Cornwallis Island (~200 people, Fig. 18), and Grise Fiord on the south coast of Ellesmere Island (~120 people, Fig. 19). There are five permanently occupied settlements on Spitzbergen, the largest island of the Svalbard archipelago, with the main town, Longyearbyen (Fig. 20), supporting a permanent population of about 2000 people and four other settlements currently occupied year-round, of which two are mines and one is the research facility of Ny-Ålesund, on the shore of Kongsfjorden. They support an additional 500 people year-round. In Novaya Zemlya, there are several settlements on Yuzhny Island (the southern large island), most near the southern end, with the largest town, Belushya Guba (Fig. 21), supporting about 2000 people and with several hundred more resident in the other hamlets.

The coldest settlements are the Canadian villages, which are Canada's northernmost settlements. They experience only 3 months when the mean daily temperature exceeds 0°C; the mean maximum temperature in July is only 7°C and the maxima in January–March are below –30°C. The monthly mean minimum and maximum temperatures at Longyearbyen are –21°C and –13°C (Feb) and +3°C and +7°C (Jul) and at Belushya Guba, –19°C and –11°C (Feb) and +3°C and +12°C (Jul). These two towns are among the warmest places in the Arctic Ocean islands.

Fig. 19 Grise Fiord, Ellesmere Island, a small community in the Canadian high Arctic (Google Earth Pro, 2018).

Fig. 20 Longyearbyen, Spitzbergen, the largest settlement in Svalbard (Google Earth Pro, 2018).

In addition to the permanent settlements, temporary camps come and go throughout the islands, weather stations exist on all the archipelagos (e.g., Eureka, Canada; [Fig. 22](#)) and minor military facilities exist in the Canadian islands, as well as on all of the Russian archipelagos, but not on Svalbard, which has been declared a demilitarized zone ([Koivurova and Holienčin, 2017](#)). Novaya Zemlya, a former nuclear weapons test site, still supports substantial permanent military bases. Recently, Russia has enlarged military facilities on Alexandra Land, Franz Josef, stationing year-round, combat-ready troops there ([RFE, 2015](#)).

Conservation

The Arctic being among the most remote places on Earth does not confer immunity from human activities that threaten ecosystem maintenance. Because existing terrestrial ecosystems on the Arctic Ocean islands have very low productivity, they will take a long to

Fig. 21 Belushya Guba, Yuzhny Island, the main town of Novaya Zemlya (Google Earth Pro, 2018).

Fig. 22 Weather station at Eureka, Ellesmere island * (Google Earth Pro, 2018).

recover, once disturbed. Potential sources of disturbance include tourism, oil and gas exploration and exploitation, facilities relating to transportation, especially those relating to the northern Sea route along the Siberian coast, and increased militarization in the wake of increasing East–West tension.

Resource Extraction

Coal mining has been ongoing in Svalbard since the late 19th century and has been the major force in creating a permanent human population there. Russian interests continue to mine coal, although activity is less than in the 20th century. A small amount of mining has been carried out in the Canadian islands, with the Polaris mine on Little Cornwallis Island producing more than 20 million tons of zinc over 21 years. It closed in 2002. As of 2018, a new lead-zinc mine is being developed on Yuzhny Island, Novaya Zemlya by the ARMZ Uranium Holding Co. and is due to begin production in 2023 (Staalesen, 2018).

Mining affects the environment through the related disturbance, as well as disruption of drainage patterns. Vegetation characteristics and schedules of snowmelt can be noticeably altered by road dust (e.g., Auerbach et al., 1997), but a Canadian study found few negative effects of mining activities on birds within 1 km of the mine footprint (Smith et al., 2005). Some birds of prey nest on rock faces or infrastructure from mining activities and appear resilient to moderate levels of human disturbance

(Swem Jr., 1996). Indeed, some birds of prey may benefit from the artificial lighting, food subsidies and nesting substrate offered by resource extraction infrastructure. Further study is needed to better understand the effects of disturbance and habitat degradation related to mining at local and regional scales.

Potential oil and gas reserves have been identified on or close to all the arctic archipelagos (Meneley, 2008, Craighill, 2015, Klett, 2017, Marex, 2017, Nilsen, 2017). Widespread oil and gas exploration took place in the Queen Elizabeth Islands of Canada from 1968 to 1987 (Meneley, 2008), but despite the discovery of 17 oil or gas fields, no commercial exploitation has ensued. Although exploration was proposed in Baffin Bay, southeast of Devon Island, permission was withheld by Government of Canada on environmental grounds (Davidson, 1981) and the area has subsequently been given protection as part of the Tallurutiup Imanga National Marine Conservation Area (Doyle, 2017). Exploration is currently ongoing in the Barents, Kara and Laptev seas, but to date the only commercial production, in the southern Barents Sea, is far from Svalbard. No commercial wells have been developed on land in any of the islands, but the development of adjacent shelf seas looks very likely.

Oil and gas exploration on land, like mineral exploitation, can significantly degrade both terrestrial and aquatic habitats. The shallow wetlands of the Arctic are sensitive to disturbance of hydrology: Oil and gas extraction can induce subsidence, seismic exploration can lead to channelization and disruption of water flow patterns, and infrastructure and road dust can affect snow melt and permafrost (Jorgensen et al., 2010). Despite technological advancements in seismic exploration, these activities continue to significantly degrade tundra habitats (Kemper and Macdonald, 2009). In addition, industrial activities can lead to locally enriched populations of predators, indirectly impacting local breeding birds (Liebezeit et al., 2009). Birds such as ivory gull and gyrfalcon are known to be affected by low-level aircraft over-flights, such as those associated with oil and mineral exploration (Platt, 1977; Mallory et al., 2008). These and other secondary effects greatly expand the area impacted by resource extraction activities.

Tourism and Other Human Disturbance

Ecotourism is increasing in the Arctic, and human visits to colonies and important breeding areas for birds are increasingly frequent. Disturbance from aircraft, cruise ships, boats, and humans can affect the reproductive success of birds by causing eggs or chicks to fall from breeding ledges on cliffs (e.g., for Thick-billed Murres: Curry and Murphy, 1995) or by leaving eggs vulnerable to predators when parents temporarily desert their nests (e.g., eiders and murres). Likewise, terrestrial mammals may be forced to leave foraging areas. Disturbance of wildlife by aircraft, ships and other vehicles is becoming an increasingly important concern among northern wildlife managers and residents.

Pollution

Most of the harmful pollutants that are released in large quantities at lower latitudes, such as agricultural pesticides, are not used in the Arctic. Industrial chemicals, such as Polychlorinated Biphenyls (PCBs), may be released near communities and development sites, but the effects are usually localized. However, within the Arctic, a substantial risk of pollution comes from chemicals transported over long distances, entering into Arctic environments through atmospheric deposition, ocean currents, and river outlets (e.g., Macdonald et al., 2000; Braune et al., 2005). Through the process of bio-magnification as they ascend the food chain, some pollutants threaten species at the top of the food chain, such as marine mammals, seabirds and especially polar bears (Norstrom et al., 1998).

Some industrial chemicals, such as PCBs, have been regulated since the 1980s but others, such as flame retardants (PBDEs) that are used in computers, car parts and upholstery were not controlled until after 2000. The presence of these compounds in Arctic wildlife is decreasing (Braune et al., 2015a, b), but heavy metals such as mercury and cadmium remain a concern for some species (e.g., Provencher et al., 2014; Braune et al., 2014) and the pathways by which they enter arctic systems are not well understood (Macdonald et al., 2000). In the case of mercury occurring in the Arctic, the most likely source is East Asia, transported by upper atmosphere winds and deposited with precipitation (Braune et al., 2014). Future changes to food webs may affect contaminant exposure, as species adjust their diets and feed higher or lower on the food chain (Braune et al., 2015a). Data exist for only a handful of Arctic species, but the effects of pollutants on arctic wildlife are potentially widespread.

As shipping through the Arctic increases, birds in marine habitats face an increasing risk from chronic oil pollution and accidental spills. Chronic pollution can lead to oiling of individual birds, but may also threaten birds indirectly, through food chain effects (Wiese and Robertson, 2004). Some species, including Common and King Eiders, forage on benthic invertebrates where hydrocarbons may reach dangerous levels (Meador et al., 1995). The risks to wildlife from accidental oil spills are substantial everywhere but are greatest in the Arctic where cold water temperatures, ice cover and periods of darkness limit the dispersal and decomposition of oil and complicate clean-up options (Arctic Council, 2009). When birds or marine mammals concentrate in one place, such as when the entire Canadian population of Pacific common eiders stages in the Southeast Beaufort Sea while on spring migration, risks may extend to whole populations.

Military Installations

Because military arrangements are not usually subject to any local political control, the enforcement of environmental regulations for military bases is more difficult than making the equivalent arrangements for civilian developments. The northern island of

Novaya Zemlya, used from 1955 to 1990 for nuclear explosion testing, is still largely under military control. The proliferation of military installations in the high Arctic archipelagos is likely to complicate any future actions for ecosystem protection.

Protected Areas

Currently, the amount of land area within the Arctic archipelagos covered by Protected Areas (International Union for the Conservation of Nature (IUCN) protection categories I-IV) is much higher than in the Arctic as a whole (Huntington, 2013). Both Wrangel Island and Franz Josef Land are completely protected: Franz Josef as part of the Russian Arctic National Park, which also includes northern Novaya Zemlya, amounting to 7% of that archipelago, and Wrangel Island is a State Nature Reserve. Svalbard contains several Protected Areas, amounting to 65% of the land area, while in the Canadian archipelago two National Parks amount to 10% of the total land area. Neither Severnaya Zemlya nor the New Siberian Islands have protection at this level at present, but the area protected for all archipelagos combined is approximately 110,000 km², 17% of the total land area, which compares with 11% for the entire area defined as Arctic by the Convention on Arctic flora and Fauna (Huntington, 2013).

Climate Change and the Future of the High Arctic Fauna and Flora

Global warming is especially acute in the Arctic, where air temperatures have risen two to three times as fast as those elsewhere on Earth over the past 30 years (Pachauri and Reisinger, 2007). Arctic glaciers in Greenland and the Canadian islands are in rapid retreat (Rignot and Kanagaratnam, 2006; White and Copland, 2018a, b). Advances in the timing of Arctic spring sea ice break-up (Parkinson and Cavalieri, 2008), and substantial increases in both summer and winter air temperatures at many Arctic stations (Tedesco et al., 2009), are well documented. Arctic-adapted plants and animals may be affected directly, through susceptibility to elevated temperatures and other climatic changes (e.g., Gaston et al., 2002 found heat and water stress caused avian mortality in warm years in northern Hudson Bay, while Anctil et al., 2014 showed that higher rainfall increased nestling mortality of Arctic-breeding Peregrine Falcons *Falco peregrinus*). For most organisms, however, indirect effects, through changes in ecosystem structure (e.g., reduced prey, increased predation, competition, parasitism and disease) are likely to have a greater impact (Ganter and Gaston, 2013).

Although climate change poses a threat to all the world's ecosystems, those of the high Arctic are especially vulnerable because, being limited to the northern fringes of the continents, they have no way to find refuge as distributions shift northwards. However, the high Arctic islands, especially those beyond the swimming range of terrestrial vertebrates (all of those dealt with here), provide a special case where some of the potential effects of climate change may be delayed. Southern predators, of which mammals such as *Lynx lynx* spp., red fox *Vulpes vulpes* and various Mustelidae (*Martes*, *Mustela*, *Neovison*, etc.) have the greatest potential for disrupting current ecosystems, may not be able to spread across water barriers. Once seasonal ice cover disappears, they will not be able to access these remote islands unless inadvertently imported by people (Gaston et al., 2012). In this context, increasing tourism, development and military activity pose a real threat to biosecurity and ecosystem integrity.

The most distant archipelagos (Svalbard, Franz Josef) are likely to see only slow and selective immigration of southern plants and insects (Coulson et al., 2002), especially those taxa with low dispersal capabilities (e.g., plants with heavy seeds, nonflying animals). Moreover, the fact that these islands will continue to be surrounded by cool seas will prevent them from experiencing extreme temperatures characteristic of continental land-masses. Consequently, they may provide us with the best opportunity available for protecting the characteristic Arctic fauna and flora.

Unless we decide to deliberately introduce absent species to Svalbard and other remote islands, our best option for the defense of the high Arctic flora and fauna will be in the Canadian archipelago. These islands are the most extensive and have the widest range of native plants and animals among the Arctic Ocean archipelagos. Placing a "cordon sanitaire" around them, by rigorous exclusion of potential southern invasive species, may provide the best opportunity to allow the biotic communities of the high Arctic to persist in the face of climate warming. To achieve this goal, awareness of the risk from species invasions and the development of systems for inspection of ships, aircraft and cargoes arriving in the high Arctic islands will be necessary. The time for action is now.

Abstract

The Azores is an isolated archipelago that is home to a unique biodiversity. However, their native biotas are being affected by different drivers of global change, mainly by land-use changes and fragmentation, introduction of exotic invasive species and climatic changes. The combined effects of these factors lead to changes in habitats structure and composition, the spread of exotic fauna and flora, and the impoverishment of native endemic species. Most of the Azorean endemic species were recently assessed for IUCN and a large fraction of the endemic arthropods have a status of conservation concern, including Critically Endangered, Endangered and Vulnerable species, which confirms an ongoing process of extinction debt that most probably will lead to the extinction of many species. One important step for designing and implementing conservation strategies that mitigate these impacts is having a deep knowledge of changes on abundance and range-size contraction and expansion. A long-term monitoring strategy is already in place in the Azores, but future actions should include implementing a “Global Island Monitoring Scheme” for the long-term coordinated survey and monitoring of native island biotas.

The Azores Archipelago

The Azores archipelago, lying on the North Atlantic Ocean, (39°43′23″N [Corvo]—36°55′43″N [Santa Maria]; 24°46′15″W [Formigas islets]—31°16′24″W [Monchique Islet—Flores]) is composed of nine islands and some islets, aligned along a WNW-ESE direction (Fig. 1). These islands are organized in three groups: the western group, including Corvo and Flores islands; the central group including Faial, Pico, Graciosa, São Jorge and Terceira islands; and the eastern group including São Miguel and Santa Maria islands, plus the Formigas islets (Fig. 1). The Azores archipelago is rather isolated, being far away from both Europe (1641 km) and North America (2985 km) continents, with Madeira archipelago being the nearest land (965 km). Within the archipelago, Pico and Faial islands are the less isolated (circa 6 km from each other). Regarding islands’ area, São Miguel is the largest island (745 km²) and Corvo is the smallest (17 km²). Pico reaches the highest altitude (2350 m abs) while five of the other islands have elevations around 1000 m asl and Graciosa island presents the lowest altitude (405 m asl) (Table 1).

All islands are oceanic of recent volcanic origin, but unlike for Hawaii or the Canary Islands, the age of the Azores is still under debate. According to França et al. (2003) (citing several authors) the oldest known geological ages of the Azores islands range from 8.12 Ma (Santa Maria) to 0.3 Ma (Pico). However, a recent study by Ramalho et al. (2017) supports a complex evolutionary history of Santa Maria, with a first emergence 6–5.8 Ma, followed by subsidence from 5.3 to 4.1 Ma, and a subsequent renewed volcanic activity (4.1–2.8 Ma) and an uplift (from 3.5 Ma to the present). Other recent studies also give younger ages than initially thought for the islands of Terceira, São Miguel and Graciosa (Hildenbrand et al., 2014; Larrea et al., 2014; Sibrant et al., 2015).

According to the Köppen Climate Classification (based on the period from 1971 to 2000), the prevalent climate in the Azores is temperate, with no dry seasons and mild summers (Cfb). Nevertheless, climate ranges from temperate, with hot and dry summers (Csa) (e.g., coastal areas of Faial and Graciosa, the west of Pico, the south and east coast of Terceira, part of the southern coast of São Miguel and west of Santa Maria) to the Tundra climate (ET) of Pico Mountain (above 1600 m). Santa Maria and Graciosa are the driest islands and the prevalent climate in these islands is temperate with dry and warm summers (Csa and Csb) (Agência Estatal de

Fig. 1 Location of Azores in the Atlantic (*top*) and the nine islands (*bottom*).

Table 1 Geographic and climatic characteristics of the Azores.

<i>Island</i>	<i>Area (km²)</i>	<i>Maximum altitude (m asl)</i>	<i>Total annual rainfall (mm)</i>	<i>Mean annual temperature (°C)</i>
Santa Maria	97	587	775	17.5
São Miguel	745	1105	1027	17.3
Terceira	400	1021	1126	16.7
Graciosa	61	405	845	17.2
São Jorge	244	1053	974	17.3
Pico	445	2350	974	17.3
Faial	173	1043	974	17.3
Flores	141	911	1716	17.0
Corvo	17	720	1145	17.5

Geological age refers to the oldest known reference (see text for more details). Total annual precipitation and average annual temperature refer to periods of 13 years for Graciosa, 20 years for Corvo and Flores and 30 years for the remaining islands. For Pico and São Jorge there is no data available, so the same values of the neighboring island of Faial are considered. *Note:* Most geographical features are reported according to Forjaz et al. (2004). Climatic data are according to IPMA (Portuguese Institute of the Sea and Atmosphere) from weather stations located at: Santa Maria-Aeroporto (100 m asl), São Miguel-Ponta Delgada (35 m asl), Terceira-Angra do Heroísmo (74 m asl), Graciosa-Santa Cruz (27 m asl), Faial-Horta (60 m asl), Corvo-Village (28 m asl), Flores-Aeroporto (34 m asl), (<http://www.climaat.angra.uac.pt/>).

Meteorología & Instituto de Meteorologia, 2011). At low elevation, the total annual rainfall ranges from 775 mm/year in Santa Maria (Eastern group), to 1716 mm/year in Flores (Western group) (cf. Table 1). However, in the central higher elevation areas of many islands, climate models estimate that rainfall may reach more than 4000 mm/year. At low elevations, the range in mean annual temperature is low (between 16.7°C and 17.5°C). Nevertheless, mean annual temperature may go as low as 10.8°C (at 900 m asl), or 6.2°C (at 2000 m asl) (Azevedo et al., 2004; Elias et al., 2016).

The most recent checklist of Azorean biota includes a total of 6112 terrestrial species and 6164 subspecies, including 452 endemic *taxa* (Borges et al., 2010a). Humans have introduced many species, especially vascular plants, where introduced species reach more than three quarters of the total number of species. However, the percentage of endemism for vascular plants, if only indigenous species (native and endemic) are considered, is one of the highest in Macaronesia (35% in Azores, 20% in Madeira, 39% in Canaries, 23% in Cabo Verde; Gabriel et al., 2014).

At the time Azores was first discovered by humans (15th century), the archipelago was mainly covered by forests (Frutuoso, 1978, 1981, 1987). Considering the work of Elías et al. (2016), it is possible to draw a picture of the potential vegetation of the islands by this time. Many flat coastal areas may have been covered by *Erica-Morella* woodlands, while *Picconia-Morella* forests should have dominated the lowlands, up to 300 m asl. Lowland and sub montane forests (the Azorean Laurel forests, dominated by *Laurus azorica*) probably covered more than two thirds of the islands, from 300 m to 600 asl. Above the *Laurus* forests, between 600 m and 1000 asl, *Juniperus-Ilex* forests and *Juniperus* woodlands would have covered most of the areas. In the higher areas, *Calluna-Juniperus* scrublands would cover mountain ridges and *Calluna-Erica* scrublands and *Calluna* scrublands would occupy Pico Mountain, above 1200 m asl as they do today. In the midst of these vascular species, larger or smaller areas of peat bogs would occur (cf. Allorge and Allorge, 1946).

Unfortunately, native habitats have been subject to remarkable modification and disturbance since human colonization, and natural vegetation became almost extinct at low and middle elevations (Table 2) (see Fig. 2). Nowadays, native vegetation is found mainly above 500 m asl and most of the remaining forests are montane cloud forests, surviving mainly in Terceira (Fig. 3), Pico and Flores islands. These unique habitats are rich in endemic species including most of the 452 known endemics. For instance, based on the most detailed inventories of Azorean forests, the 20 most pristine native forest areas include 23 out of the known 26 Azorean endemic spiders and 43 out of the 78 endemic beetles (Borges et al., 2005a, 2010a; Ribeiro et al., 2005). The Azores are also the only archipelago in Macaronesia with large peat formations.

The Azores are a Portuguese autonomous region with a Parliament located on Faial Island and the main political institutions located in São Miguel, Terceira and also Faial islands. Human population in the archipelago is ca. 242,000 (Table 2). São Miguel Island is, by far, the most populated island, followed by Terceira (cf. Table 2). The economy was traditionally dominated by fisheries and agriculture (especially dairy-cattle products such as milk and cheese), but in the last decade, tourism is becoming one of the main drivers of Azorean economy.

Drivers of Biodiversity Erosion

According to the Millennium Ecosystem Assessment (MEA, 2003), drivers of change are “any natural or human-induced factor that directly or indirectly causes a change in an ecosystem. A direct driver unequivocally influences ecosystem processes. An indirect driver operates more diffusely by altering one or more direct drivers.” (MEA, 2003, p. 49). Physical and biological drivers are considered direct drivers, while demographic, economical, sociopolitical, cultural and religious, scientific and technological factors, are considered indirect drivers of change (Nelson et al., 2006). The Azores have suffered the long-term effects of many human impacts that have shaped its current diversity. Below we address some of the most important ones.

Table 2 Present-day human population size and native vegetation cover in the Azores archipelago.

Island group	Island	Estimated present-day human population size	Present-day native vegetation cover (%)	Present-day native forest cover (%)
Oriental group	Santa Maria	5578	7.8	0.1
	São Miguel	131,609	8.7	0.4
Central group	Terceira	55,833	14.2	5.9
	Graciosa	4780	0.4	0.0
	São Jorge	9674	14.7	1.2
	Pico	14,806	13.7	2.1
	Faial	15,063	9.4	1.3
Occidental group	Flores	3995	32.9	11.1
	Corvo	425	51.3	0.0
	Azores	241,763	12.8	2.5

Habitat Changes

Native Azorean habitats have a long history of natural changes, that were mainly induced by volcanic eruptions and the Pleistocene climatic changes (Rull et al., 2017). However, human-induced changes have played a dramatic role in shaping the current biodiversity of the Azores (Rull et al., 2017). Historical records show that Portuguese sailors discovered and explored the Azores from the early XV century. However, it has been suggested that humans could have settled in the Azores prior to the official discovery of the archipelago (e.g., Connor et al., 2012; Gabriel et al., 2015; Rull et al., 2017). If that was the case, those settlements were temporary, since there are no historic accounts of human presence in the islands by Portuguese sailors and settlers.

The most eastern islands, Santa Maria and São Miguel, were the first to be discovered by Diogo de Silves around 1427. After that, all the remaining islands were sequentially discovered and populated by the Portuguese. The availability of drinking water sources

facilitated the colonization, but the main reported challenge was the progression of settlers due to the complex orography of the islands, furthermore covered with dense forests (e.g., Frutuoso, 1978, 1981, 1987). It is noteworthy that the Portuguese settlers were wise in many decisions regarding land occupation, for instance using lava fields for wine production, better soils for agriculture and wheat, and grasslands in the highest elevations (Silveira, 2013). However, human pressure was not innocuous and there is evidence that by 1700 most of the land below 300 m elevation was already transformed, and that by 1850, native vegetation was mostly restricted to areas above 500 m. In fact, the temporal sequence of native forest destruction followed the conic shape of these volcanic islands (e.g., Silveira, 2013).

In modern times, the most dramatic changes occurred during the two World Wars, with deforestation occurring at mid and higher elevations due to the need of wood as energy source. Thus, by 1950, a major enterprise was performed to reforest mid elevation areas with the exotic fast-growing tree, *Cryptomeria japonica*, already used in the islands since the XIX century. Additional deforestation of native forests occurred between 1970 and 1990 for the implantation of high elevation semi-natural pastures and additional *Cryptomeria japonica* plantations (Fig. 4).

A more recent period of intense changes occurred between 1980 and 2000, with the mechanization of agriculture boosted by European agricultural policies, and the creation of large areas of intensive pasture monocultures at high elevations (e.g., in Terceira, Pico and Flores islands). These changes implied, for instance, that from 1998 to 2013 Pico Island suffered an increase of 3% of the surface occupied by intensive pastures (Gil et al., 2018). The consequences of these changes for biodiversity are not completely known, but the richness of species from different taxonomic groups (e.g., bryophytes, ferns, arthropods) decreases from forests to grasslands, while semi-natural pastures have more complex vegetation that benefit phytophagous insects and spider diversity (Borges and Brown, 2001). All these indicators provide indirect evidence of the loss of biodiversity that occurs in intensive managed grasslands. Paradoxically, there is a strong predominance of intensive pastures and maize in areas theoretically unsuitable for this purpose in Terceira Island, boosted by the recent expansion (2001–11) of pasture intensification to areas more suitable for forests (Reis and Dentinho, 2015).

Azorean urban areas are mostly located in coastal areas. Indeed, many Azorean cities are close or within coastal biodiversity hotspots, producing impacts on the coastal biota (Bertocci et al., 2017). The increasing pressure of urbanization led to the destruction and degradation of many coastal habitats, and almost to the extinction of its original ecosystems (Elias et al., 2016). Many species currently persist in much reduced patches of coastal habitats, notably some invertebrates (Borges et al., 2018b) and plants, such as the emblematic *Azorina vidalii*. Together with the development of agriculture and urbanization came an increase in the transport networks that has been growing in the Azores during the last 50 years. This too is a driver of the degradation and fragmentation of native habitats, fostering the spread of invasive species, particularly impacting pristine native forests at mid to high elevation and cave ecosystems highly disturbed by new routes (Borges et al., 2012).

As a consequence of these major human changes, pristine native forests are currently restricted to less than 5% of the Azores area, being completely absent in Graciosa and Corvo islands and with larger and most well preserved areas occurring mainly in Terceira, Pico and Flores islands (Gaspar et al., 2011).

Fig. 4 The monoculture of the industrial plantation of *Cryptomeria japonica* in Azores (Credit: Paulo A. V. Borges).

The consequences of these land-use changes in Azorean biodiversity were investigated for some taxonomic groups, namely arthropods (e.g., Borges et al., 2008; Cardoso et al., 2009; Florencio et al., 2015, 2016; Rigal et al., 2018) and vascular plants (Marcelino et al., 2013). In both groups, exotic species tend to proliferate and indigenous species to decline with increasing anthropogenic disturbance and management intensity. In general, the fragmentation of the Azorean landscape and the prevalence of human modified habitats have promoted the expansion of soil epigeal exotic species adapted to native habitats. However, the same does not apply to the arboreal canopy arthropod communities, still dominated by endemic and native non-endemic arthropods, suggesting that native forest canopies are still acting as physical barriers to the colonization by exotic fauna (Florencio et al., 2016).

Several anthropogenic habitats are now the dominant land cover in the Azores, and therefore some of these habitats (e.g., semi-natural pastures, exotic forests and intensive pastures) surround many native forest fragments. Consequently, source-sink dynamics in Azorean arthropod communities constitute an important ecological process that operates at both spatial (Borges et al., 2008; Cardoso et al., 2009) and temporal scales (Matthews et al., 2019). Indeed, many species common in a given habitat are frequently being observed as pseudo-rare or tourists in other habitats (Borges et al., 2008). However, true rare endemic species (i.e., species with restricted distribution, low abundance and/or high habitat specialization) are also important in the native habitats and many of them are threatened (Borges et al., 2017a). Because of the lack of source-sink dynamics at the archipelago scale, Single Island Endemics (SIEs), i.e., endemic species restricted to only one island, are those under more severe threat.

Regarding vascular plants, Marcelino et al. (2013) observed that endemic and native non-endemic species could occur with some frequency in anthropogenic habitats. However, there is no empirical evidence that indicates that those populations are sustainable or contributing for the long-term survival of those species. Although some bryophyte species are present in different ecosystems, the highest richness is found inside native forests and near humid zones, while urban areas include only a small proportion of the mosses and liverworts that occur in the Azores (Gabriel and Bates, 2005; Gabriel et al., 2011).

Intense land-use change dynamics can also have an impact on species abundance, as demonstrated by studies on the Azorean arthropod communities; in native habitats, communities tend to approach a log-normal distribution (i.e., those in equilibrium), with some species being common, many species having intermediate abundance and many being rare species. In more disturbed habitats, like exotic forests and highly transformed pastures, communities are dominated by a few common species and many rare species, following a logseries distribution instead (Matthews et al., 2014b).

The extent of the impacts of land-use changes on insect pollinators was recently investigated with surprising results. Picanço et al. (2017) showed that Azorean flower-visiting insect communities are highly simplified across an entire disturbance gradient, with little difference between habitats. These results have two potential outcomes: (1) endemic and native insect pollinator successfully adapted to new anthropogenic habitats and are providing essential ecosystem services in agro-ecosystems; (2) in the absence of strong exotic competitors, indigenous flower-visiting insects expand their range, also facilitating the expansion of a large number of exotic plant species.

Cryptomeria japonica plantations are one of the most important anthropogenic habitats in the Azores. This gymnosperm was planted massively in the archipelago in the mid-20th century, and the impact of these plantations was positive to a certain point, because they mitigated soil erosion, improved water retention and served as a wind protection for cattle in pastures. However, the negative impacts are considerable since, depending on the compass of plantation, there is almost no understory vegetation and the arthropod fauna is very poor (Cardoso et al., 2009). In a recent study, Ferreira et al. (2017) showed that, contrary to expectations, the replacement of native forests by *Cryptomeria japonica* plantations did not affect litter decomposition in Azorean streams. However, these authors observed some changes in aquatic hyphomycete communities arriving from *Cryptomeria japonica* forest, suggesting that there is the need to create a riparian buffer of native vegetation in *C. japonica* plantations.

The clearing of native vegetation for the creation of anthropic habitats have already led to the extinction of many species (Alcover et al., 2015; Terzopoulou et al., 2015; Rando et al., 2017) and to the prediction of alarming future extinctions in extant habitats (Triantis et al., 2010), with direct consequences for the structure and functioning of many ecosystems. For some taxa like ground-beetles, the communities in Azorean native forest are unbalanced with the current absence of species of intermediate abundance, and the dominance of few species, some of them exotic (Boeiro et al., 2018), which is possibly a consequence of massive extinctions of large bodied species (Terzopoulou et al., 2015).

Habitat changes and biodiversity loss on Azores are still occurring today, not only because of land use changes, but also due to the spread of invasive species and climatic changes (see below).

Human Induced Climate Changes

Climate variation has been always an important driver of natural changes in the Azorean biota (Norder et al., 2019). However, human-induced habitat changes were of overwhelming importance in shaping Azorean ecosystems in the last 600 years of human occupation (Connor et al., 2012; Silveira, 2013). Current research in Azores indicates all Azorean islands lost precipitation below 500 m in the last 20 years (Eduardo Brito Azevedo, Pers. Comm.). The number of dry summers are also increasing with impacts at all elevations, but mostly at lower altitude. Moreover, despite no changes in total precipitation, there is a marked concentration of pluviometry in shorter periods. The expectations for the next decades are the intensification of these changes that will tend to be more important also at high elevations, and in particular islands with few remnants of native vegetation (Corvo, Graciosa, and Santa Maria islands).

The recent and future impacts of human-induced climatic changes on island biodiversity are now well recognized (Harter et al., 2015; Ferreira et al., 2016; Patiño et al., 2016). The most common responses to climatic changes are shifts in latitudinal and elevational ranges (Harter et al., 2015), which in Azores will have a huge impact on the long-term sustainability of many endemic hyper-humid forest adapted species of bryophytes (Ferreira et al., 2016; Patiño et al., 2016), arthropods and vascular plants (Ferreira et al., 2016). Indeed, many of those species will endure a reduction of their range size and, in some cases, current protected areas will not be effective tools for their long-term protection (Ferreira et al., 2019). Taking into consideration that more than half of the extant native forest-dependent arthropod endemic species might eventually be driven to extinction due to a process of extinction debt, related to major past and current land-use changes, fragmentation and forest loss (Triantis et al., 2010), the combination of these factors with climatic changes might be dramatic for the diverse endemic arthropods. It is worth reinforcing that the volcanic origin of the islands tends to create conic volumes; thus the upper elevations have much less area than the lower ones, which restricts even further the ability of species to colonize and survive on the remaining fragments with adequate climatic conditions.

Predictions based on climatic modeling, data on habitat fragmentation and information about species dispersal limitations, further forecast strong reductions (up to 94%) of important native forest areas for functional connectivity of fragmented populations of six endemic insects in Terceira Island (Aparício et al., 2018). The fact that many specialized ground-beetles (Borges et al., 2006) and bryophytes (Gabriel and Bates, 2005) are dependent of hyper humid conditions in high elevation native forests, make these species particularly vulnerable to potential changes in relative humidity. Indeed, the luxuriant bryophyte and fern communities of the high elevation native forests will be highly impacted if the number and intensity of droughts increase in Azores, as predicted by most climatic models (Patiño et al., 2016). The impacts for the forest structure are difficult to envisage, but important ecosystem services related with nutrient cycling and water retention may be highly impacted.

Exotic Species and Invasive Alien Species

Invasive Alien Species (IAS) are currently the major driver of biodiversity erosion in Azores. The fact that a large proportion of Azorean terrestrial seed plants (around 70%) and arthropods (around 45%) are exotic (Borges et al., 2005b), created an opportunity for a large number of them becoming invasive species, spreading not only in the native forest habitats, but also in freshwater and urban ecosystems (see more below). The success of exotic and invasive species in the Azores is related with several factors:

- (a) the Azorean native flora and fauna are species poor (Triantis et al., 2012), which creates the ecological opportunity for newcomers to settle down. According to Darwin's naturalization hypothesis, newcomers are more likely to become invaders when close related species are missing, a trend that is known to occur in the Azorean flora (Schaefer et al., 2011a).
- (b) the lack of natural enemies in Azorean native biota, which creates an "enemy free space";
- (c) the Azorean temperate mild climate, favoring the successful adaptation by species with wide ecological features and tolerances;
- (d) the fact that native pollinators may be visiting and pollinating exotic plants (Picanço et al., 2017), while native birds help in the dispersal of seeds of some IAS plants, which enhances the success of exotic and IAS plants in Azores;
- (e) the long coexistence between pasture grasses and maize, and their close taxonomic relationship (both are grasses), which host several exotic insects and insect pests, allowing these ecosystems to behave as a stepping stone in the invasion of native habitats;
- (f) the role of urban parks and gardens as a source of exotic ornamental species, which include a vast number of species, many of which have escaped to the wild (Bogas, 2003; Gabriel, 2019).

The high diversity of exotic species present in the Azorean Islands is reflected also by their dominance in many habitats, particularly in anthropogenic habitats (Cardoso et al., 2009; Schaefer et al., 2011a; Marcelino et al., 2013), but also, to some extent, in native forest, such as in the case of soil arthropods, particularly Collembola (Cicconardi et al., 2017). Noteworthy, an invasive earthworm species was even successful in colonize and establish in hostile conditions in volcanic soil on São Miguel (Azores) (Cunha et al., 2011).

Notwithstanding, the canopies of Azorean native forests still hold some level of resistance to the spread of exotic arthropods (Borges et al., 2008; Florencio et al., 2016), which may be related with the difficulty of exotic species to adapt to the architecture and micro-habitats of Azorean tree canopy. However, paradoxically, exotic species enlarged the ecological functional space in Azorean ecosystems, as exotic species differ in their functional profile from indigenous species in all studied land-uses (Rigal et al., 2018). Therefore, exotic species may contribute positively to the maintenance of some ecosystem functions in Azorean agro-ecosystems.

Exotic arthropod species are already well integrated in epigeal habitats, such that they are well mixed with native species when plotting the abundance of each species with their-occupancy (Rigal et al., 2013). However, it is also important to recognize that in Azorean native forests, introduced exotic species have lower densities, less spatial variance in these densities, and occupy fewer sites than native non-endemic and endemic species (Gaston et al., 2006; Borges et al., 2008). The high diversity of exotic arthropod species in native forest was observed mostly in sites located on the edge of still well preserved forest patches in Terceira (Borges et al., 2006). However, in many Azorean Islands the application of an Index of Biotic Integrity that incorporates several diversity metrics (Gaspar et al., 2011), shows that exotic arthropod species are having enormous impacts particularly on small fragments of native forest.

Concerning freshwater environments, Raposeiro et al. (2017b) showed that fish exotic predators introduced in Azores were the most important factor affecting the chironomid fly assemblages in lakes from S. Miguel Island. The presence of fish also affects other macroinvertebrates on permanent ponds in Terceira Island (Florencio and Lamelas-López, 2016).

In the last decades, the impact of IAS seed plants was particularly dramatic on Azorean native forests, forming dominant stands, altering the three-dimensional structure of native forests, sometimes replacing them entirely (see e.g., [Hortal et al., 2010](#) for a study with *Pittosporum undulatum* impacts). Based on an observation of invasion patterns of IAS plants in Azores, [Hanski \(2016\)](#) named this process as “A Green Tsunami,” since IAS plants are occupying large fractions of native forest. However, the impact of invasive plants on the structure and composition of soil biota in Azores remains to be empirically investigated.

It is currently established that IAS mammals, particularly rats and feral cats, were the drivers of extinction of many endemic birds in the Azores ([Alcover et al., 2015](#); [Rando et al., 2017](#)) and are still severely affecting populations of breeding birds, through predation on eggs, nestlings, and adults ([Monteiro et al., 1996](#); [Hervías et al., 2013](#)). In addition, rats are vectors or reservoirs of *Leptospirosis* spp., constituting a major threat to Azorean farmers’ health, including fatal human cases ([Collares-Pereira et al., 2000](#); [Esteves et al., 2014](#)).

In urban environments, in addition to rats and some common nuisance invertebrates (e.g., cockroaches, ants), four species of termites were recently identified in the archipelago, and three of them are promoting major economic impacts in Terceira, São Miguel and Faial islands ([Austin et al., 2012](#); [Guerreiro et al., 2014](#); [Duarte et al., 2018](#)). Particularly relevant is the impact of the drywood termite *Cryptotermes brevis*, for which the control measures in place are inefficient and the estimated costs for the future in terms of building treatments of rebuilding are in order of 1406 million euros ([Guerreiro et al., 2014](#)). More successful may be the control of the two subterranean termites for which there are some projects to eradicate the current two hotspots in Praia da Vitória (Terceira Island) and Horta (Faial Island).

In Macaronesia, one important initiative related to IAS, was the creation of the TOP100 Macaronesian IAS ([Silva et al., 2008](#)), a list that includes the most dangerous invasive species to Macaronesian native species and habitats. Most of the 100 IAS species identified include seed plants and vertebrates, but there are also some invertebrates. In due time, most of these species were included in a legal diploma (Annex IX of Regional Legislative Decree n.º 15/2012/A from 2 April), that aims to protect Azorean biodiversity.

Pollution and Contamination

The Azorean economy is currently dominated by dairy cattle production based on intensive permanent or semi-permanent pastures. These human activities difficult water infiltration and retention in the subsoil, and constitute a source of water pollution due to the use of fertilizers ([Borges et al., 2009](#)). Maize-pasture rotation is now widespread at both low and mid elevations, both farming systems serving only for dairy-cattle feeding. The massive use of chemicals for fertilization led to a continuous nutrient enrichment and pollution of all Azorean lakes and small temporary and permanent ponds (e.g., eutrophication and presence of nitrates in freshwater) ([Dentinho et al., 2008](#); [Cruz et al., 2015](#)), and are still polluting soils and freshwater with immense unmeasured impacts on biodiversity. For instance, high chlorophyll-*a* concentrations in water created unfavorable conditions for macroinvertebrates in permanent ponds from Terceira Island (Lamelas-López pers. comm). Moreover, changes in the chlorophyll-*a* concentrations can affect leaf litter decomposition in Azorean lakes, with potential consequences for nutrient cycling ([Raposeiro et al., 2017a](#)).

Fertilizers also have negative impacts on the arthropod communities in agricultural lands. [Santos et al. \(2005\)](#) studied both arthropod pests and their natural enemies in fruit orchards in Terceira Island, and found that the toxicity and frequency of use of pesticides had a negative effect on all arthropod groups, particularly on those that control pest species (i.e., spiders and parasitoids). Recent studies investigating the impact of agriculture practices on soil pollution (accumulation of trace metals in soil matrix) and microbial activity showed that agriculture intensification affected the soil microbial activities by decreasing the abundance of microbial biomass, with a consequent impact in organic matter decomposition and nutrient cycling ([Parelho et al., 2016](#)).

Indirect Drivers of Biodiversity Erosion

The processes leading to biodiversity erosion are not entirely dependent on physical and biological drivers. The role of indirect drivers should also be acknowledged, as both facilitators and hinderers of conservation and management of biodiversity.

In spite of the ongoing biodiversity crisis (e.g., [Cardinale et al., 2012](#); [Dobbs et al., 2014](#)), and the difficulties in halting it (e.g., [Sharman and Mlambo, 2012](#)), there are evidences that a new environmental paradigm is settling across the world ([Dunlap et al., 2000](#)), with human population showing a broad concern towards biodiversity and ecosystems preservation. The Azorean people are no exception. [Silva and Gabriel \(2009\)](#), studying a sample of 600 persons, stratified by island (São Miguel and Terceira) and place of residence (urban or rural), have shown that Azoreans generally endorsed the values of the New Environmental Paradigm, especially in what refers to the existence of other species (“Plants and animals have as much right as humans to exist”; 95,5% agreement). A favorable perspective towards biodiversity was also found among 1528 students (12–18 years old) from all the islands of the archipelago, who chose “Species protection” as the top investment area among 20 different themes, including the protection of groundwater or fire prevention ([Gabriel et al., 2012](#)).

There appears to be a contradiction between these shared perspectives supporting biodiversity, and the behaviors regarding land-use changes, exotic invasive species and contamination of the soils. This contradiction, or gap, between attitudes, values, beliefs, norms and pro-environmental behaviors has often been reported (e.g., [Kollmuss and Agyeman, 2002](#)) and different factors may help to explain it, including human perception, time scale and complexity inherent to ecological systems. For instance, the Azores are mostly perceived as “natural” for both residents and tourists ([Arroz et al., 2018](#)), while many invasive species occupy large areas in all the islands. On the other hand, the pace of ecological destruction (slow and gradual) is difficult to perceive at human scale and

ecosystems tend to be complex, with intricate relationships, for instance, the increased levels of nitrogen on the soil, may hinder the growth of bacterial films inside caves (Riquelme et al., 2015). Besides, emotional non-investment on environmental matters may lead to lack of knowledge and awareness and resistance against non-conforming information (people want to protect plant species—including invasive plant species), while a number of emotional reactions, such as apathy, denial and rational distancing may deter the preservation of natural ecosystems, thus leading to biodiversity erosion.

Conservation Biogeography

The design and establishment of proper conservation actions needs to be based on adequate data on the distribution, abundance and biology of the species and habitat characteristics intended to preserve. In Azores, the BALA project (1999–2004) is an exemplary case in which occurrence and abundance data were gathered using standardized sampling techniques in the soil and canopy of 100 plots in seven Azorean Islands, to respond to multiple community ecology and macroecological questions (see review in Borges et al., 2011). Similar efforts for other taxa in Azores are absent, but some approximate cases are: (i) the studies of the impact of anthropogenic disturbance in several islands on both vascular plants (Marcelino et al., 2013) and arthropods (Cardoso et al., 2009; Florencio et al., 2015, 2016), and (ii) the role of elevation on the diversity of Azorean bryophytes (Henriques et al., 2017b) and vascular plants (Coelho et al., 2016; Henriques et al., 2017c).

These large scale surveys have allowed addressing several biodiversity shortfalls for these islands (Cardoso et al., 2011; Hortal et al., 2015) in a systematic way, contributing also for the design of conservation policies in Azores. The best example is the TOP100 management priority species for the European archipelagos of the Macaronesian region (Azores, Madeira, and the Canary Islands) (Martín et al., 2010), and the ranking of Azorean protected areas based on a Biotic Integrity Index (Gaspar et al., 2011).

Research performed in the Azores in the last decades has also led to advances towards solving the “Linnean shortfall” (i.e., the need to describe the unknown species and revise the taxonomy of groups of species poorly known). For instance, 24 out of the known 26 endemic Azorean spiders have been described since 1989 (Borges and Wunderlich, 2008; Crespo et al., 2013, 2014) and a comprehensive checklist of Azorean terrestrial and marine biota is available (Borges et al., 2010a). However, despite the high rate of taxonomic descriptions in the last decades, many species are awaiting discovery and taxonomic description (Lobo and Borges, 2010; Schaefer et al., 2011b), and for some taxonomic groups this knowledge is still quite poor (e.g., Fungi, Lichens, Acari, Diptera, Hymenoptera; see Borges et al., 2010a). The Azorean Biodiversity Portal E-infrastructure (<http://azoresbiportal.uac.pt/>; Borges et al., 2010b), has been of great relevance to support the continuous exposure of Azorean biota to potential taxonomic revisions, contributing also to a public awareness on the relevance of Azorean biodiversity.

In addition to taxonomy, two very important sources of data are needed for proper conservation, the knowledge on the distribution and abundances of species (i.e., the so-called the Wallacean and Prestonian shortfalls, respectively; Cardoso et al., 2011; Hortal et al., 2015). In Azores, the study of the distribution of species at different spatial scales has been properly dealt in important initiatives already mentioned above for arthropods (the BALA project; Borges et al., 2006, 2011), vascular plants (Marcelino et al., 2013; Elias et al., 2016) and bryophytes (Gabriel and Bates, 2005; Aranda et al., 2011). The spatial variation of species abundances (Prestonian shortfall) was studied in detail only for Azorean arthropods in both native forests (Gaston et al., 2006) and other land-uses (Rigal et al., 2013). Evidence indicates that there is a positive relationship between species distributions and their relative abundances, and that exotic species are already well integrated in the native forest floor communities. However, exotic species tend to occur in less number of sites and have lower mean abundances (Gaston et al., 2006). One interesting future research avenue will be to investigate whether species incidence data (presence/absence) could be used to predict the spatial abundance of species. Jiménez-Valverde et al. (2009) found that this is possible but only for some few widespread exotic spiders in Terceira Island, which difficult the use of species distribution models (SDMs) as surrogates of detailed species abundances in space.

Arthropods were also used to study other important abundance metrics, which helped understanding the impact of seasonal variations on species relative abundances (Borges et al., 2017b), the spatial scaling properties of species abundance distributions (Borda-de-Água et al., 2017), the relevance of a species relative abundance metric (GAMBIN model) in the study of species relative abundances (SADs) (Matthews et al., 2014a, 2014b), and its application in biogeographical studies (Fattorini et al., 2016).

In terms of conservation management, the detailed knowledge of species abundances allowed the ranking of protected areas in Azores based on arthropod data (Borges et al., 2005a; Gaspar et al., 2011). Based on these studies the Azorean government created news protected areas and the legislation on species and habitats was improved (RAA, 2012).

Probably of high relevance is all the species distribution data digitized in the AZOREAN BIODIVERSITY PORTAL initiative (Borges et al., 2010a,b) at a 500 × 500 m grid, that allowed performing the IUCN assessments (red listing) for bryophytes, vascular plants and arthropods in Azores in the last 3 years. This data also led to other kind of spatial research responding to both ecological (Henriques et al., 2016), evolutionary (Steinbauer et al., 2016) and conservation questions related with reserve selection (Fattorini et al., 2012; Vergílio et al., 2016) and the impact of climatic changes in Azorean flora and fauna (Ferreira et al., 2016; Patiño et al., 2016).

For the first time in Azores, a long-term monitoring program is in place since 2012, to investigate the impact of climatic changes on the distribution and abundance of arthropods from the native forest (Borges et al., 2017b; Matthews et al., 2019).

The Hutchinsonian and Raunkiaeran shortfalls were originally coined by Mokany and Ferrier (2011) and Hortal et al. (2015) respectively. The Hutchinsonian shortfall relates to the lack of knowledge about the life history (and biotic tolerances), whereas the Raunkiaeran shortfall relates to species functional traits, and both shortfalls hamper proper biodiversity conservation. In many cases,

we lack also complete information on species interactions with other species (Eltonian shortfall). Advances in these critical fields about the knowledge of species biology are only now being tentatively filled with the creation of functional traits databases for bryophytes (Henriques et al., 2017a,d), vascular plants (Schaefer et al., 2011a; Heleno and Vargas, 2015), and arthropods (Whittaker et al., 2014; Rigal et al., 2018).

Present Answers and Future Prospects

Azorean Islands constitute unparalleled natural laboratories for testing the impact of global changes on biodiversity. A high proportion of endemic species are restricted to small fragments of native forests, and with few exceptions (e.g., canopy arthropods; Florencio et al., 2016) they are sensitive to biotic disturbance such as invasions, land-use changes and climatic changes. This creates the perfect setting to test the response of ecological communities to disturbance, and its effects on ecosystem processes. Investigating the spatial replacement of species (i.e., turnover) and richness difference components of beta time, Matthews et al. (2019) showed that exotic arthropod species have high temporal beta turnover than native species, which is due to source-sink dynamics related with the surrounding anthropogenic habitats.

Exotic species often alter ecological processes (Simberloff et al., 2013) and cause severe biodiversity loss. Nevertheless, these species may also provide ecosystem services: exotic arthropods can contribute to important ecological functions in agroecosystems (Rigal et al., 2018) and exotic plants can increase microbial activity (Vilà et al., 2011), introduced natural enemies can control pests (Heimpel and Mills, 2017), or provide ecological “insurance” after the decline of native species (Weissmann and Schaefer, 2017). Understanding the impact of invasive species is particularly important on islands, because of their unique biodiversity and vulnerability (Patiño et al., 2017).

According to Aparício et al. (2018) ensuring the creation of corridors between native vegetation areas should be a priority as an adaptation response to climate change effects in Azores. One important step for designing and implementing conservation strategies that mitigate these impacts is having a deep knowledge of changes on abundance and range-size contraction and expansion. A long-term monitoring strategy is already in place in the Azores, but future actions should include implementing a “Global Island Monitoring Scheme” for the long-term coordinated survey and monitoring of native island forest biota (Borges et al., 2018a).

Abstract

Given the important role of climate on species distributions, climate change is expected to have effects on biodiversity conservation. Biodiversity on the Caribbean Islands is characterized by a broad range of distributions, from cosmopolitan species to many rare and endemic species that occupy limited geographic areas. Species most vulnerable to climate change include rare and endemic species in wet upper mountain cloud forests and species in restricted coastal habitats vulnerable to warming oceans and sea level rise. Tropical montane cloud forests harbor endemic and endangered species from many taxa. Rising temperatures, reduced precipitation, decreasing relative humidity, and increasing intensity of hurricanes all present conservation challenges for protecting these species as migration upward to favorable climates is not possible. Coastal habitats are local biodiversity hotspots throughout the Caribbean. Rising and warming seas change conditions by increasing salinity of landward habitats, increasing the likelihood of coral bleaching, and increasing storm surge effects throughout the coastal zone. The high density of people and coastal infrastructure in the Caribbean Islands creates scenarios that limit potential landward migration of species and habitats in response to changing coastal conditions and present challenges in prioritizing land use and conservation.

Introduction

The Caribbean has been widely recognized as a biodiversity hotspot (Myers et al., 2000; Roberts et al., 2002; Mittermeier et al., 2004; Shi et al., 2005). The region encompasses 2.75 million square kilometers and includes over 7000 islands and cays. The islands of the Caribbean form an arc running from the Yucatan peninsula of Mexico extending east and south to the northeastern coast of South America (Fig. 1). Principle island groups include the Greater and Lesser Antilles, the Bahamas, Cayman Islands, and Turks and Caicos Islands. There are 13 sovereign island nations and 12 territories with ties to Europe and the United States. The majority of the Caribbean Islands are relatively small, only 13 have an area over 1000 km². The terrestrial land area of the Caribbean Islands is ca. 230,000 km² and nearly 87% of this is in the five largest islands of Cuba, Hispaniola, Jamaica, Puerto Rico, and Trinidad. Together these have a land area of over 200,000 km². Key components to the biodiversity of the Caribbean include the high level of endemism on individual islands or island groups, the diversity of habitats, a long history of human introduction of species, and the tropical climate of the region.

The coastal and marine ecosystems are extremely important to the cultural, economic, and ecological fabric of Caribbean societies. Near shore environments of coral reefs, seagrass beds, beaches, mangroves, rocky shorelines, and estuaries create a matrix of habitats that are some of the most biologically diverse on earth. Coral reefs anchor the marine end of the ridge to reef continuum. They serve as a living barrier that attenuates the wave energy of storms on green and gray shoreline infrastructure. They are sensitive to both ocean warming and acidification and vulnerable to climate change wherever they occur. The Caribbean includes nearly 8% of the world's coral reefs (Bryant et al., 1998), which covers about 26,000 km² (Burke et al., 2004). Seagrass beds and mangroves cover about 66,000 km² and 11,560 km² respectively (Miloslavich et al., 2010). Over 12,000 species have been reported to occur in marine habitats in the Caribbean, dominated by mollusks, crustaceans, and fish (Miloslavich et al., 2010).

A complex matrix of terrestrial habitats influenced by climate, substrates, topography, and land use history supports a reported flora of 12,847 native and introduced species (Acevedo Rodríguez and Strong, 2008; Lugo et al., 2012), with a native flora of ca. 11,000 species (Acevedo-Rodríguez and Strong, 2007) including nearly 8000 endemic vascular plant species (Francisco-Ortega et al., 2007). Terrestrial vertebrates have been reported to include 1342 species, including 564 bird, 520 reptile, 189 amphibian, and 69 mammal species (Anadón-Irizarry et al., 2012). Vertebrate faunal diversity includes high levels of endemic species and genera as a result of speciation on islands and distinctive and isolated habitats such as the upper mountain cloud forests, fragmented

Fig. 1 The Insular Caribbean. From: González, G. and Heartsill-Scalley, T. (2016). Building a collaborative network to understand regional forest dynamics and advance forestry initiatives in the Caribbean. *Caribbean Naturalist*. Special Issue No. 1:245-256.

subtropical dry forests, and thousands of small dry islands and rocky cays. Less well documented but species rich groups of lichenized and other fungi, insects, spiders, and snails also show high levels of endemism due to insular isolation and the rich matrix of Caribbean Island habitats. In Puerto Rico alone over 1180 species of lichens have been recognized (Mercado-Díaz, 2009), with new endemic genera recently described (Mercado-Díaz et al., 2013; Mercado-Díaz et al., 2014) and estimates that the real lichen diversity of the island may reach about 2000 species—nearly 50% of the current checklist for North America (Mercado-Díaz et al., 2015). Fontenla (2003) reports endemism in butterflies of over 35% on the island of Hispaniola, and over 12% among the reported 1011 butterfly species for the Caribbean. The high degree of endemism and rarity across a wide range of taxa have implications as to the vulnerability of species to climate change.

Climate Change

Historically, the Caribbean region has experienced relatively stable seasonal rainfall patterns, moderate annual temperature fluctuations, and a variety of extreme weather events, such as tropical storms, hurricanes, and droughts. Variations in climate over the last 10,000 years have included drier conditions at the end of the last deglaciation (10–7 KY BP), wetter conditions in the early Holocene persisting over 4 k years, and a return to drier conditions in the late Holocene (Hodell et al., 1991). These changes are correlated with orbitally induced variations in seasonal insolation. However, the Caribbean climate is changing due to new atmospheric conditions in the Anthropocene, and is projected to be increasingly variable as levels of greenhouse gasses in the atmosphere increase. Climate change parameters affecting biodiversity in the Caribbean islands include the patterns of precipitation, increasing day and night time air temperatures, increasing sea surface temperature and acidity, sea level rise, and the predictability, frequency, and intensity of extreme climate events such as hurricanes and drought.

Rainfall

Caribbean islands typically experience a dry season from November through April and a wet season from May through October (Granger, 1985; Oliver, 2005; Taylor and Alfaro, 2005; Karmalkar et al., 2013). A characteristic of the Caribbean climate is what is known as the midsummer drought (MSD) (Magaña et al., 1999), which is a dry period (not necessarily a drought) during the wet season resulting in a bimodal cycle of precipitation. The timing and duration of the MSD varies across the Caribbean from early June in parts of the eastern Caribbean to late July around Cuba and the Bahamas, to non-existent in some eastern islands (Magaña et al., 1999; Curtis and Gamble, 2008; Gamble et al., 2008; Karmalkar et al., 2013). The timing, duration, and existence of the MSD in the Caribbean is important ecologically and as measures for modeling and downscaling projected climate for the Caribbean (Stoner et al., 2013; Hayhoe, 2013; Ryu and Hayhoe, 2014). The amount of rainfall varies considerably from drier northern to wetter

southern islands, and mountainous topography interacting with the northeasterly trade winds creates steep gradients in rainfall over short distances on many islands (Granger, 1985; Sobel et al., 2011; Daly et al., 2003). These gradients drive many patterns in species distributions, ecosystem functions, and biodiversity in the Caribbean (Gould et al., 2006; González et al., 2013). Recent downscaling efforts (Bowden et al., 2018; Bhardwaj et al., 2018) are providing projected climate data at fine scales and allowing researchers to model potential effects on crops and ecosystems (Fain et al., 2018; Khalyani et al., 2016). An analysis of the potential effects of climate change on 200 plant species in Puerto Rico suggests that environmental suitability are projected to increase for low-altitude dry and warm climate species while it decreased for the high-altitude colder and wet climate species (Khalyani et al., 2019) (Fig. 2).

Air Temperature

Rising temperatures have been manifested as both increasing night time minimum temperatures and as a higher frequency of extreme heat days (Van Beusekom et al., 2015; Gould et al., 2018). Climate projections indicate these trends will likely continue and accelerate (Khalyani et al., 2016; Bhardwaj et al., 2018). Projections of more hot dry days, longer periods without rain, and warming night time temperatures have implications for direct and indirect effects on species (Khalyani et al., 2016). There are a number of endemic species adapted to the cool, wet, cloudy climates of the higher mountains in Puerto Rico, Jamaica, Hispaniola, and Cuba. Many species from several taxa will likely be adversely affected as rainfall decreases, temperature rises, and relative humidity drops below threshold levels for the formation of cloud forests in the Caribbean (Gould et al., 2018; Miller et al., 2018; Helmer et al., 2019) (Fig. 3). Secondary effects of rising temperatures and reduced rainfall include changes in the phenology of fruiting, flowering, and leaf fall that have effects on habitat conditions, nutrient cycling, plant reproductive fitness, and animal populations (PRCCC, 2013; Gould et al., 2018). Additionally, unusually dry vegetation increases the risk of fire (Monmany et al., 2017; Van Beusekom et al., 2018a).

Sea Surface Temperature

Ocean surface waters have warmed globally by about 0.13 °F (0.07 °C) per decade between 1900 and 2016 (Jewett and Romanou, 2017). From 1955 to 2016 the waters of the northeast Caribbean increased at a rate of 0.23 °F (0.13 °C) per decade, and over the last two decades, the sea surface warming rate has reached 0.43 °F (0.24 °C) per decade (Boyer et al., 2013; Gould et al., 2018) (Fig. 4). One of the responses to ocean warming is bleaching of adult coral colonies. Prolonged or severe periods of high temperatures and extended coral bleaching can result in colony death. In 2005, a mass bleaching event, driven by 12 weeks of temperatures above the normal local seasonal maximum, affected the entire Caribbean region, resulting in the loss of 40–80% of the coral cover in the region (Donner et al., 2007; Selig et al., 2013; Gould et al., 2018) (Fig. 5).

Sea Level Rise

Since the middle of 20th century, relative sea levels have risen by about 0.08 in. (2 mm) per year on average along the coasts of Puerto Rico and the United States Virgin Islands. However, rates have been slowly accelerating since the early 2000s with an acceleration by a factor of about three starting in 2010–11. This recent acceleration agrees with what has been observed along the

Fig. 2 Changes in the number of tree species as calculated from using the Spatially Explicit Species Assemblage Modeling framework (Guisan and Rahbek, 2011) for future periods under high (A–D) and low (E–H) carbon emission scenarios. Fig. 4 Annual time series from 1993 to 2016 of atmospheric carbon dioxide (CO₂; black line), sea surface temperature (red line), and seawater pH (blue line) for the Caribbean region. (Gould et al., 2018; <https://nca2018.globalchange.gov/chapter/20#fig-20-5>.)

southeastern U.S. seaboard, and rates of global and regional relative sea level rise are projected to continue to increase substantially this century, largely dependent on the amount of future greenhouse gas emissions. Relative sea levels are projected to rise by about 0.8, 1.2, or 2.8 ft in low, intermediate or high emissions scenarios, respectively, by 2050 across the region compared to levels in 2000 and by about 1.6, 3.6, or 10.2 ft, respectively, by 2100 (Zervas, 2009; Sweet et al., 2017; Gould et al., 2018) (Fig. 6).

Fig. 5 Coral reefs are sensitive to sea surface temperatures. The condition of coral reefs has a big effect on biodiversity as so many species depend on healthy reef. The severity of effects increases as CO₂ levels and sea surface temperatures rise. If conditions stabilized with concentrations of atmospheric CO₂ at 380 ppm (parts per million), coral would continue to be carbonate accreting, meaning reefs would still form and have corals. At 450–500 ppm, reef erosion could exceed calcification, meaning that reef structure is likely to erode and coral cover is likely to decline dramatically. Beyond 500 ppm, corals are not expected to survive. (Gould et al. 2018; <https://nca2018.globalchange.gov/chapter/20#fig-20-6>).

Fig. 6 Sea level rise trends in Puerto Rico and the U.S. Virgin Islands for the period 1962–2017. Projections are shown under three different scenarios of intermediate-low (1–2 ft), intermediate (3–4 ft), and extreme (9–11 ft) sea level rise. (Gould et al. 2018; <https://nca2018.globalchange.gov/chapter/20#fig-20-6>).

Biodiversity and Conservation

Protected area networks are a widely adopted strategy for conserving biodiversity and to mitigate the adverse effects of climate change (Dudley et al., 2010; Naughton-Treves et al., 2005). About 20% of the land base of the insular Caribbean is designated as protected area (UNEP-WCMC and IUCN, 2019). In this region, islands vary in the degree of protection from less than 5% on the island of Barbados to 60–70% on the islands of Guadeloupe and Martinique (Table 1). However, under new and changing climate conditions, species are shifting their distribution ranges, which means protected areas today may not be effective in the near future (Bustamante et al., 2018; Armsworth et al., 2018).

Island geography, sea level rise, and development can limit options for species migrations. As an example, in recent decades in Puerto Rico residential development increased adjacent to most of the island's protected areas, limiting capacity to expand and

adapt to new climatic conditions (Castro-Prieto et al., 2017, Fig. 7). Within montane protected areas, limited ability for upward migration along elevational climatic gradients increases the vulnerability of upper montane species. For example, as climate changes, climate constrained infectious disease may be driving changes in amphibian species ranges within natural areas. Analyses of historical records and recent frog acoustic samplings in the protected El Yunque National Forest (EYNF) in the Luquillo Mountains of Northeastern Puerto Rico suggest shifts in anuran distributions, where incidence of disease moves upward, and low elevation areas have lost at least six anuran species in the last 25 years (Campos-Cerqueira and Aide, 2017). Similarly, in a study of bird distributions along the elevational and climatic gradient in these mountains, most of the bird species studied (72%) did not present elevational shifts in their ranges but there is evidence of a significant upward shift in the range of eight species (Campos-Cerqueira et al., 2017).

Sea level rise affects terrestrial habitats through salinization of coastal wetlands and aquifers, through increased rates of erosion, and through inundation. These represent changes in habitat characteristics important in governing species distributions and biodiversity. Potentially, marine habitats can shift landward or increase in growth to adapt to rising seas, and terrestrial species can migrate landward to accommodate new salinity gradients. However, the coastal zones throughout the Caribbean are where most people live and build roads, airports, hospitals, hotels, and power plants. Infrastructure represents a significant barrier to the landward migration of species adapting to sea level rise (Yu et al., 2019). The conflicts between development and natural resource protection will only increase as natural areas are reduced by sea level rise and coasts are hardened to protect infrastructure and mitigate erosion (Fig. 8).

In addition to shifting climate means affecting species distributions, extreme climate events such as high temperatures, hurricanes, droughts, and flooding are all projected to increase with a warming climate, and species distributions will be affected (Van Beusekom et al., 2018b; Wunderle, 2018; Lloyd et al., 2019; Khalyani et al., 2019; Helmer et al., 2019). Extreme events can increase mortality rates and, under new climatic regimes, promote shifts in the distribution of habitats and species.

Protected areas are one of several mechanisms that can support biodiversity conservation in what has been described by Castro-Prieto et al. (2019) as an integrated system for the conservation of nature (Fig. 9). This includes recognizing four mechanisms in addition to protected area networks, i.e., the role of laws and regulations that protect species, habitats, and ecosystems;

Fig. 7 Housing net change and the rate of change within 1-km of the protected areas in Puerto Rico (Castro-Prieto et al., 2017).

Fig. 8 Hawksbill turtle nest near Humacao, Puerto Rico, hemmed in by housing development and subject to hurricane damages from nearby infrastructure. Photo credit Carlos E. Díez González.

Fig. 9 An envisioned integrated system for the conservation of nature in Puerto Rico, which includes the protected areas and other land conservation mechanisms available in the island.

land use policies and regulations; incentive programs; and individual and community based actions. This integrated approach is important considering the magnitude of climate change effects and the recognition that management and effectiveness of biodiversity protection within protected area networks varies widely (Kairo et al., 2003; Visconti et al., 2019). Research is ongoing as to how well protected areas accomplish different aspects of biodiversity conservation, particularly in light of climate change (Rincón-Díaz et al., 2018; Armsworth et al., 2018; Maharaja et al., 2019). The integrated approach also recognized that biodiversity is a component not only of wildlands and protected areas, but also of working lands. Climate change has effects on biodiversity relevant to food security and agriculture. For example, forecasts based on long-term honey yield records and bioclimatic variables suggest a reduction on average yield and in areas suitable for honey production in Puerto Rico under multiple scenarios of climate change (Delgado et al., 2012). Additionally, projected climate trends suggest that increases in mean temperature and decreases in precipitation could result in the reduction of highly suitable growth conditions for *Coffea arabica* in this century (Fain et al., 2018). Balancing food security, conservation and economic development while dealing with climate risks is an ongoing issue across the Caribbean Region (Knowles et al., 2015; Gould et al., 2017; Gould et al., 2018).

Conclusions

The nature of governance of natural resources is particularly diverse in the Caribbean. Support for conservation and climate related research and adaptation practices from North American, Latin American, and European research institutes, governmental agencies, Universities, and local and global conservation organizations is extensive if not always coordinated (Gould et al., 2018, Fig. 10). Working across boundaries can be one way to reduce climate change vulnerabilities. As an example, an inter-agency effort allowed the development of a comprehensive protected areas database and the quantification and mapping of other conservation mechanisms that contribute to a larger picture of land conservation in Puerto Rico (Castro-Prieto et al., 2019).

Climate change risks are increasing and effects are being experienced by natural resource managers in the Caribbean. Islands don't have much space for large protected areas or for shifting and expanding their current boundaries. Targeted mechanisms can make the best use of resources—i.e., protecting those rare habitats from disturbance or implementing management to maintain some kind of condition will help maintain species of interest and biodiversity. There is a long history of information on climate and conservation research in the Caribbean. However, it is not always used for planning and management applications. Efforts to deliver

Fig. 10 Location of selected organizations working on climate risk assessment and management in the Caribbean region. Regional efforts to address climate challenges include the implementation of adaptation measures to reduce natural, social, and economic vulnerabilities, and actions to reduce greenhouse gas emissions (Gould et al., 2018; <http://nca2018.globalchange.gov/chapter/20#fig-20-18>).

science-based knowledge to agencies, universities, institutions and land managers dealing with vulnerable species and habitats will help organizations to act fast and adapt to climate change and weather variability. Regional and locally based vulnerability assessments focused on effects on biodiversity, modeling of projected climate change effects species that provide key ecological/and agricultural services, and assessing the effectiveness of adaptive practices are important components to reduce vulnerability to climate change. Actions that reduce the vulnerability to future risks include preparing for disturbance with nurseries and mitigation methods. Integrating species of interest with infrastructure in coastal and agricultural or working lands. Aligning best practices with mechanisms, incentives, and education of conservation practices in working lands that integrate biodiversity (e.g., multi-story cropping, alley cropping, corridors) (Álvarez-Berríos et al., 2018). Monitoring and managing to reduce cumulative effects. Collaborating internationally to share capacity, regional vulnerability assessments, and knowledge. Enjoying what we have—value and appreciation are key to conservation. Research needs include better quantifying values provided by nature, additional area covered by downscaling climate data, and modeling linking downscaling to species distributions, ecosystem services, and climate vulnerabilities.

Given the high level of biodiversity throughout the Caribbean, it is not easy to prioritize what is most at risk. Two priority areas from an example in Puerto Rico are found across the Caribbean (Fig. 11). They include wet mountain tops and cloud forests, and the marine and terrestrial coastal zone. The high number of endemics in island cloud forests, and the lack of ability to migrate from mountain tops, makes this a key habitat in the conservation of biodiversity. Additionally, species adapted to the coastal zones throughout the Caribbean are subject to multiple stressors of warming oceans, acidifying oceans, rising seas, and increasing constraints of development and infrastructure. Coastal species are often more cosmopolitan than cloud forest species, with relatively fewer endemics. However, coastal habitats tend to be local biodiversity hotspots due to the matrix of marine, wetland, and upland habitats. Sea level rise and salinization often trap coastal habitats between rising seas and infrastructure, limiting capacity for inward migration, and putting coastal biodiversity at risk and a priority for biodiversity conservation.

Acknowledgments

Thanks to Edgardo González and Sandra Soto Bayó for figure on habitats in Puerto Rico vulnerable to climate change. Thanks to Carlos E. Díez González for turtle and coastal erosion photographs. Thanks to Olga Ramos for figure identifying the Insular Caribbean. All research at the USDA Forest Service International Institute of Tropical Forestry is done in collaboration with the University of Puerto Rico.

Abstract

The offshore cays around the main islands of Puerto Rico, St. Thomas, St. John, and St. Croix are largely uninhabited and provide habitat for threatened, endangered, at-risk, and species of greatest conservation need including many resident and migratory species of seabirds, shorebirds, endemic reptiles, and plants. Management is limited by insufficient resources, capacity, and a mixture of ownership (federal, Commonwealth, Territorial, private NGO, and private), making regional planning a challenge. Invasive species are the dominant short- and long-term threats to these systems including invasive plants that alter habitat conditions and invasive mammals (e.g., mice, rats, goats) that kill native fauna and degrade habitats. Recreational and commercial uses by humans, as well as marine debris and accumulations from harmful algal blooms, pose a significant threat to crucial habitats and key conservation species, especially in the coastal zone. In the longer term, the cays ecosystems and fauna are expected to show high exposure and sensitivity with limited adaptive capacity, depending on the type of island, to the impacts of climate change. Current projections highlight substantially altered rainfall patterns and extensive drought, as well as extreme sea level rise (beyond 3 m by 2100 under the worst scenarios) and more frequent or intense hurricanes. The impacts of sea level and precipitation in particular were used to develop future scenarios to compare and contrast effects on focal species and coastal habitats. The scenarios and impacts were then used to suggest potential adaptation strategies.

Introduction

There are over 750 offshore islands within the U.S. Caribbean surrounding the main islands of Puerto Rico and U.S. Virgin Islands (USVI) of St. Thomas, St. Croix, and St. John (Fig. 1A and B). The diversity of these islands is influenced by geology, location (windward, leeward), adjacent ocean bathymetry, proximity to a larger land mass, elevation/topography, size, accessibility, and historical use. The terms island (*isla*), islet (*islote*), cay (*cayo*), and rock (*roca*, *peñón*, *piedra*) often prefix island names interchangeably but there appears to be no exact criteria for their use. An islet can refer to any small island, whereas interestingly, the word cay (or *cayo* in Spanish) in Puerto Rico often refers to a small, low island or bank composed of sand and coral fragments, whereas in the USVI

Fig. 1 (A) Regional map of the Caribbean framed by southern North American, Central America, and northern South America to provide reference for the location of the U.S. Caribbean, i.e., Puerto Rico and the U.S. Virgin Islands. (B) Map of the primary cays of the U.S. Caribbean mentioned in the text.

cays more commonly refer to the larger higher vegetated islands. Islands within the U.S. Caribbean can be classified into four types based on their formation or composition: (1) sand and coral cays; (2) mangrove cays; (3) volcanic and volcanoclastic; and (4) limestone. Each type is described in detail below.

Although some cays have been developed for human use, the majority are largely uninhabited and support many species, including some that are threatened, endangered, or endemic. In addition to providing wildlife refugia, the offshore islands are also important to society. Humans use the terrestrial and aquatic areas surrounding the islands for tourism, recreation, the extraction of resources (mining, fishing and forestry) and to market their scenic value. The excessive uses over time and high demand for the limited space on these islands has resulted in far reaching impacts such as invasive species (especially mammals such as rats, mice, mongoose, deer, feral cats, pigs, and goats, but also reptiles such as common iguanas, as well as non-native invasive plants) and anthropogenic disturbances due to direct use or plastic pollution reaching the cays.

There has been an extensive, and highly controversial, history of U.S. military use or lease for bombing practices from 1939 to 1975 within the Culebra Island archipelago and Desecheo Island (García-Muñoz, 1991, CINWRC-PR, 2011) and Monito Island. Additionally, the eastern end of Vieques Island, and many of the adjacent cays were used for various military practices (including bombing) from the 1940s to 2003.

Fig. 1 (continued).

Potential impacts stemming from the effects of the current climate crisis include sea level rise, projected increases in the intensity and duration of droughts, warming air and water temperatures, intense coral bleaching and disease, ocean acidification, saltwater intrusion, and increased intensity and frequency of tropical storms and hurricanes (Gould et al., 2018). The species and habitats that sustain island ecosystems are highly vulnerable to the combined effects of these impacts.

Effective conservation and adaptation of these island systems will require a regional approach. However, the ownership, legal status, and use of cays and islets in the U.S. Caribbean is highly complex making regional planning challenging. Most of the larger islands are located within marine managed areas (MMAs) (Schärer-Umpierre et al., 2014). These are designated as Natural Reserves or Wildlife Sanctuaries administered by Puerto Rico Department of Natural and Environmental Resources (PR-DNER) (e.g., Mona, Monito, Caja de Muertos, Fig. 1) and the U.S. Virgin Islands Department of Planning and Natural Resources (USVI-DPNR), National Wildlife Refuges (NWR) administered by the U.S. Fish and Wildlife Service (USFWS) (e.g., Desecheo, in Puerto Rico, Navassa between Haiti and Jamaica, and Green Cay and Buck Island in the USVI), national parks administered by the U.S. National Park Service (NPS) (e.g., Buck Island Reef National Monument off St. Croix and several cays around St. John in the USVI), and one National Estuarine Research Reserve. In addition, several Natural Reserves (NR) and their marine extensions (e.g., Northeast Ecological Corridor, Arrecifes de la Cordillera; La Parguera; Mona and Monito Islands and Jobos Bay), and the Culebra NWR incorporate multiple islets and cays. While not formally protected, several Critical Wildlife Areas also incorporate multiple islets including the Fajardo coastline and mangroves and adjacent cays within the Punta Petrona NR (Ventosa-Febles, 2005). In Puerto Rico some islands are privately owned including Cayo Norte off Culebra and Isla Palominos and Palominitos in Arrecifes de la Cordillera NR. Private islands are more common in the USVI, with approximately a quarter of the territory's islands in private ownership. Of 57 identified cays, 29 belong to the Virgin Islands government, 14 are wholly private, three are partially private, co-owned with an NGO or Federal entity, eight are US government owned, and three are uncertain. Notable privately-owned islands in USVI include Hans Lollik, Thatch, Great and Little St. James, and Lovango, the latter two being relatively very developed. Interestingly, there is a man-made island of fascinating origin and evolution and Box 1 provides more detail on this interesting situation. Overall, the mixture of ownership creates political and logistical challenges in developing regional management plans for species that cross political boundaries and similarly adds complexity to climate adaptation planning.

Island Type Descriptions

Sand and coral cays: Many of the small cays along the south coast of Puerto Rico have developed over surfacing coral reefs (Fig. 2). The emergent portions are created by the effects of high wave energy accumulating fragments of coral skeletons, principally Elkhorn coral (*Acropora palmata*), (Glynn et al., 1964). These emergent parts of the cays are called ramparts (Hernandez-Avila et al., 1977; Williams et al., 1999). Lower energy sites have cays composed mostly of sand, vegetation, and detritus in addition to the Elkhorn ramparts. Over time, the sediment may stabilize as beach-rock forms (cemented at water level by precipitated calcium carbonate), and the cay becomes vegetated. These islands are dynamic systems, and their shape changes considerably due to accretion and erosion during storms. Many cays are associated with a variety of fringing, patch, bank, and shelf-edge coral reefs. Cays on fringing reefs are the most common and are found throughout the northeast, east, and southern shelf of Puerto Rico. One of the best examples is Arrecifes de la Cordillera Natural Reserve (ACNR), a chain of small, low-elevation cays, rocky islets, and coral reefs stretching between Fajardo and Culebra along a shallow, submarine ridge approximately 29 km long. Some of these cays comprise oolitic (sedimentary rock formed from ooids, spherical grains of concentric layers) eolianite (rock formed by compaction and cementing of particles that have been deposited by the wind) deposits similar to those found in the Bahamas (Kaye, 1959). The rocky islets are the top of ancient dunes that were cemented by calcite. Vegetation associations on these cays include evergreen littoral forest, dry evergreen brush, rocky shores, mangroves, and sandy beach. Sand/coral cays are rare in the USVI.

Mangrove cays: Many cays along the south coast of Puerto Rico are associated predominantly with mangroves (Pittman et al., 2010). These form through a successional process originating with red mangroves (*Rhizophora mangle*) colonizing seagrass beds dominated by turtle grass (*Thalassia testudinum*) on submerged marine sands and may go through a coral reef stage. Vegetation diversity, structure, and biomass of these cays are influenced by differences in soil salinity, frequency of tidal over-wash, wave intensity, and nutrient input. Two notable mangrove cay clusters in Puerto Rico occur in La Parguera Natural Reserve (LPNR) in the southwest and at Jobos Bay National Estuarine Research Reserve (JBNERR) in the southeast (e.g., Cayos Caribe, Cayos de Barca, see Fig. 3) in Puerto Rico. The mangrove islands in LPNR have formed along fringing reefs, some of which lie up to four km from the Puerto Rico shoreline. The cays in JBNERR stretch more than five km along fringing reefs, separated by deep drainage channels (Morelock et al., 1977). Most are covered by mangroves, but some larger cays contain small areas of evergreen littoral woodland and/or secondary vegetation and hypersaline lagoons. In the USVI mangrove cays are uncommon with only a single named cay (Cas Cay) and a few islets within the Mangrove Lagoon on the southeastern side St. Thomas.

Volcanic islands: The volcanic islands are represented by Desecheo Island to the west and Culebra Island to the east of Puerto Rico and most of the islands within the northern USVI (St. Thomas and St. John, Fig. 4). The Puerto Rican Bank archipelago comprises the large islands and over 100 smaller satellite islands, separated from each other in the late Holocene era by eustatic (due to glacial melting) sea level rise (5.3–2.5 million years before present). The islands are dominantly andesite lava, lava breccia, and tuffs (Banks, 1962; Veve and Taggart, 1996). The largest of the cays contain small patches of deciduous, semi-evergreen forest, while the smaller cays are largely steep-walled rocky platforms covered by grasses and shrubs or bare rock (Figs. 4B and 5A–C). Desecheo

Box 1 Ruth Cay, USVI: Industrial destruction turns into endangered species habitat.

Ruth Island is a low-lying man-made cay off the south central coast of St. Croix, U.S Virgin Islands (Fig. B1.1). The 13 hectare island was created in 1965 through deposition of dredge spoil from construction of a shipping channel through Krause Lagoon, a large mangrove system that was effectively destroyed by this action and associated industrialization. Yet the tiny island has grown in ecological value over the decades to become a critical resource for declining species.

Fig. B1.1 Ruth Island. Credit: Google Earth <https://earth.google.com/web/>, accessed June 2019.

The island is comprised of shell and coral rubble and sand with patches of woodland, coastal scrub, and bare rubble habitats (Fig. B1.2). A salt pond has developed on the southeastern corner, surrounded by mangroves planted during mitigation efforts in the 1970s to compensate for the loss of Krause Lagoon (Lewis and Haines, 1980). Habitats on the islands are continuously undergoing vegetation succession, allowing shrublands to become dense. The wetland and woody habitats are used by a number of birds, including White-cheeked Pintails (*Anas bahamensis*) and White-crowned Pigeons (*Patagioenas leucocephala*, Fig. B1.3) that nest in high numbers on this island (55–95 pairs; McNair, 2008). Due to historical hunting pressure combined with habitat loss and non-native mammalian predators, both of these species have been designated as territorial Species of Greatest Conservation Need.

In 1990, 10 federally listed St. Croix Ground Lizards (*Pholidoscelis polops*, **Fig. B1.3**) were released on the island in a bid to expand the distribution of this critically endangered species (McNair and Mackay, 2005). Subsequent population estimates indicated an increase in individuals to 60 in 2003, and a 10-fold increase between 2003 and 2008 (McNair and Mackay, 2005; Geographic Consulting, 2011). This tiny population represents an important species refugia, being one of only four extant populations of this species.

Island is primarily fragmented volcanic rocks of early Tertiary origin (Seiders et al., 1972) that is dominated by sub-tropical dry forest and is fringed by some of the healthiest coral reefs in the region (García-Sais et al., 2003).

Limestone islands: Situated in the Mona passage to the west of Puerto Rico are Mona (5500 ha) and Monito (14.5 ha) Islands and exemplify limestone islands (**Fig. 6A** and **B**); although Anegada Island in the British Virgin Islands, far to the east, is another important and very old limestone island. Mona Island is the largest offshore island in Puerto Rican waters (**Fig. 1B**). Both Mona and

Platenberg and (B) Credit: R. Platenberg.

Monito have been separated from the main island of Puerto Rico far longer than the Culebra islands have been. Mona is a Mio-Pliocene tectonically uplifted carbonate limestone plateau (meseta) (Morelock et al., 2002; Renken et al., 2002; Frank et al. 1998; Seiders et al., 1972). This isolation has led to several endemic species, including an orchid, amphibians and reptiles such as the Mona Iguana (*Cyclura stejnegeri*) (Fig. 6C). Mona Island is dominated by sub-tropical dry forest and is fringed by well-developed coral reefs (García-Sais et al., 2003).

Ecological Value of Cays

Because of their isolation, offshore islands provide valuable refuges for flora and fauna where threats from human persecution, habitat degradation, and climate change are either lacking or evident but with the chance of being more manageable than on the mainland. For example, the largest hawksbill (*Eretmochelys imbricata*) and green (*Chelonia mydas*) sea turtle rookeries in Puerto Rico are on Mona Island and Vieques Island respectively, and leatherbacks (*Dermochelys coriacea*) nest on several of the cays off St. Thomas. Endemic species occur on the larger, more isolated islands (Mona Fig. 6A and B; Monito, Desecheo) and many of these species are also designated as threatened under the US Endangered Species Act or local regulations. Other species such as white-crowned pigeon (*Patagioenas leucocephala*; see Box 1), brown pelican (*Pelecanus occidentalis*), other seabirds, and various shorebirds regularly nest or roost on offshore islets and cays. Coastal wetlands on cays provide habitat for a variety of migratory shorebirds and water birds, along with a variety of invertebrates. Several larger cays off the north shore of St. Thomas have cliff caves and fissures that are occupied by the Antillean Fruit-eating Bat (*Brachyphylla cavernarum*), while Mona and Monito Islands were mined for bat guano during the 19th century (Frank, 1998). Many reptile species that have been extirpated from human-inhabited islands maintain remnant population on these cays, such as the Puerto Rican racer *Borikenophis portoricensis*, the federally endangered St. Croix Ground Lizard (*Pholidoscelis polops*, see Box 1), and the endemic skinks *Spondylurus* spp. Amphibians and many land birds are also absent from most of these islands due to reduced habitat complexity. In a few cases, species threatened on the mainland have been translocated to offshore islets to safeguard populations (e.g., Virgin Islands boa, see Box 2).

Seabirds are an important component of marine biodiversity as they play significant regulatory roles and enhance primary productivity in local marine, intertidal, and terrestrial environments. Cays and islets are critical breeding sites for seabirds because of the reduced predation pressure and ease of access to foraging grounds. Eighteen species of seabirds breed on at least 37 offshore islands or island clusters in Puerto Rican waters (Fig. 7A). The major seabird nesting areas in the USVI are found on about 25 of the most remote or rugged cays off St. Thomas and St. John, where their eggs and offspring are less vulnerable to predators than on the

Murry and (C) Credit: Molly Ramsey.

major islands (Pierce, 1996; Fig. 4B). The species composition of breeding seabirds varies among the cays depending upon the availability of nest sites. For example, Flat Cay and Saba Island harbor active rookeries of gulls and terns, Cockroach Cay (Fig. 4B) and Dutchcap Cay host colonies of boobies (Fig. 7B and C) and tropicbirds, and Congo Cay, Dutchcap Cay, Buck Island (St. Croix), and Green Cay (St. Croix) support nesting pelicans. Many species exhibit high site fidelity and can be found in the same sites year after year, while some species, such as the federally protected Roseate Tern (*Sterna dougallii*) utilize a complex of islands by selecting different sites on an annual basis. Except for some terns, most seabirds nest at the same colony year after year, and rarely form new colonies. These patterns in the multiple uses of islands by key species have significant management and adaptation implications as new methods may be needed to facilitate colony formation on islands with greater resilience to sea level rise, drought, and other stressors.

Offshore islands also provide valuable stopover sites and wintering grounds for Nearctic and Neotropical birds migrating along the Atlantic Flyway. They are likely to be the first landfall site that migrants encounter (Wallace et al., 1996), and function as refuges for migrants during tropical storms and hurricanes. Larger islands such as Mona can support over-wintering migrants. As the spread of invasive species and frequency of weather disruptions increases, offshore islands may become increasingly important to migratory species.

Social Value of Cays

In addition to the ecological importance of supporting high levels of unique biodiversity, the islands surrounding Puerto Rico and USVI also have social, economic, and cultural value. Their position on the coast can dissipate wave and storm energy reducing impacts to coastal communities on nearby islands. The ecosystems associated with cays and islands also provide nursery habitats for commercially important fish and invertebrates that support local artisanal and recreational fisheries. Danylchuk (2015) used acoustic tracking to define preferred shoals for bonefish and the associated recreational catch-and-release fishery around Culebra, Puerto Rico. The study shows how this depth-associated recreational fishery, of commercial importance for fishing guides and

Box 2 Case Study: Virgin Islands Tree Boa

The Puerto Rican Bank is found within the Caribbean Region, which is considered a biodiversity hotspot (Cincotta and Engelman, 2000; Helmer et al., 2002; Myers et al., 2000). This geological area encompasses the island of Puerto Rico (excluding Mona Island) and its offshore cays, the U. S. Virgin Islands (but not Saint Croix), the British Virgin Islands, and more than 180 associated small islets and cays (Heatwole and MacKenzie, 1967; Thomas, 1999), islands harbor a high percentage of endemic species and have suffered a high percentage of extinctions (Island Conservation, 2014). This unfortunate condition has promoted the implementation of diverse single species conservation initiatives aimed mainly at vertebrate species.

The endangered Virgin Islands tree boa (Fig. B2.1; Federal Register, 1970, 35:16047), *Chilabothrus granti* (Rodríguez-Robles et al., 2015), presents a disjunct distribution on the islands of the Puerto Rican Bank (Nellis et al. 1983; Mayer, 2012). Its patchiness in occupancy has been explained by pre-historical (eustatic) changes in sea level and more recently by anthropogenic disturbances (deforestation, invasive species) that have caused the population's extirpation within the species' original range (Nellis et al., 1983; Tolson, 1996). Due to its risk of extinction, a recovery project started in the mid 1980s to release captive bred offspring of founders from wild populations in Puerto Rico (Cayo Diablo) and St. Thomas and to reintroduce them to two cays near each respective locality. After twenty years, it was classified as "highly successful" due to the establishment of the two new and sustainable wild populations on protected lands (Tolson et al., 2008). To accomplish this milestone, several phases had to be completed:

Fig. B2.1 The Endangered Virgin Islands tree boa is an example of one of many threatened and endangered species that find refuge on the largely uninhabited cays of the Puerto Rican Bank, but are vulnerable to sea level rise in the long-term, invasive species and development in the short-term. Credit: M. García-Bermúdez.

1. Pre-evaluation and selection of cays according to habitat condition, presence of invasive cats, rats, and abundance of boa prey
2. Eradication of rats
3. Capture of wild boas to establish an ex situ captive breeding program
4. Release of captive born individuals in the wild
5. Long-term monitoring of released individuals for survivability and population growth

It was assumed that the translocation of Virgin Island tree boas to cays after eradicating the invasive species in Puerto Rico and the USVI, respectively, had safeguarded its recovery. However, the threats related to climate change, particularly sea level rise turned all these efforts into a stopgap action because the recipient cays are relatively low in relation to current sea level and will be impacted negatively by the projected increments in sea level and catastrophic events—hurricanes and droughts (PRCCC, 2013). Furthermore, during a recent post Hurricane Maria survey, no boas were found, and rats have recolonized the Puerto Rican cay (Island Conservation, 2018). These threats acting individually or in synergy will exacerbate the risk of extinction of the species and other components of the Caribbean biota. Therefore, a landscape approach to the recovery of these species addressing common threats (i.e., invasive species and sea level rise) to protect them is timely and urgent.

associated businesses, could be affected by sea level rise. Changes in the ecological value of these small islands, shoals, and cays can impact tourism, recreational fisheries, and the economies of coastal communities.

Historically there was extensive mining of guano, agriculture, and forestry practices on many of the region's islands. An interesting use of cays can be found at Santiago Cay off the east coast of Puerto Rico where primate research spanning over 70 years has been ongoing by the Caribbean Primate Research Center of the University of Puerto Rico. Islands also provide extensive recreational opportunities such as second homes, boating, fishing, snorkeling and scuba diving, surfing, and simply gathering to relax and barbeque (Fig. 8). Significant tourism has been developed in some of the nearshore cays with high visitation rates, local fishing charters and dive operators generating income to multiple sectors of the local economy. However, recreational use of cays can also be highly damaging to the ecological integrity of the cays and surrounding marine habitats (e.g., coral reefs and seagrass beds), representing a clear and present conflict of use.

Fig. 8 Recreational boat use of Cayo de Barca, Jobos Bay National Estuarine Research Reserve, Puerto Rico. Credit: E. Rodriguez.

In response, the PR-DNER administered a program of installation and maintenance of mooring buoys since 2004. The objective of the program is to reduce anchor damage on seagrass meadows and coral reefs. High-use and high-risk areas were assessed via aerial surveys to increase the effectiveness of placement of the mooring buoys (Fig. 8). The program successfully installed over

300 buoys (Rodríguez-Robles et al., 2015). Over time, patterns of boater use of different anchoring areas and degree of acceptance of the mooring buoys by the boaters as an alternative to anchoring can be detected through the photos.

Recreational boat use tends to peak during holidays and the most popular and high-risk locations tend to be nearby long-term docking facilities and on islands with sandy beaches. All the high use areas are associated with damages and diminished habitat quality to local corals and seagrasses and the intensity of use makes it logistically impossible to supply enough moorings (Rodríguez-Robles et al., 2015). Further, there has been a recent shift in use (2005–12 compared to 1998–2004) toward cays closer to the coast and docking areas (e.g., yacht clubs) that appears to be driven by rising fuel costs (Rodríguez-Robles et al., 2015). Thus, until economics and behaviors change, cays nearer the main island and their surrounding marine habitats are especially vulnerable to anthropogenic damage.

A similar mooring installation program was also initiated in the USVI, although the social usage patterns are different. USVI cays do not experience the high-level congregation on weekends and holidays that PR cays do; USVI cays are more exposed to ocean current, have smaller beaches or none at all, and many require technical skills to access. Rather, visitation is focused on fishing and diving activities. Historically the seabird colonies were plundered for egg collection and in response VI-DPNR installed “no entry” signage and a requirement for visitation permits for access beyond the beach and this activity has largely ended. Some locals still access the cays to hunt non-native goats that were placed decades or centuries ago as an emergency food resource. Goats and rats have been removed from the cays with important seabird nesting colonies, but goats and rats still remain on many privately-owned cays.

The accumulation of plastics carried by currents and winds towards mangrove and coastal zones of small islands is significant. These plastics are associated with the habitat degradation and direct risk of entanglement with sea turtles and seabirds that come to shore. Ingestion of the plastics that float near the islands by chicks increases their mortality, although the extent of this impact has not been assessed. Recent accumulations of large quantities of sargassum algae have been impacting the nearshore and coastal communities of islands in the US Caribbean. The weight of the algae can overcome the sea turtles that inhabit nearshore areas drowning them. Hatchling sea turtles are also affected by the sargassum accumulations off sea turtle nesting beaches increasing their mortality as they try to reach the sea. Marine organisms also perish due to the anoxic conditions that are created when the seaweed decompose, and bacteria consume most of the dissolved oxygen.

Beyond recreational use, the US military utilized many of the islands off the eastern coast of Puerto Rico (between Puerto Rico and St. Thomas), including Vieques and Culebra with sizable human populations (and very popular tourist destinations), for target shooting and bombing practice. This practice, which ended in 1975 in Culebra, and in 2003 in Vieques, due largely to public anger and objections, has left a legacy of habitat damage, pollution, and potentially live munitions within the terrestrial and shallow near-shore aquatic zones (McCaffrey, 2018). The majority of the lands were subsequently transferred from US military possession to the U.S. Fish and Wildlife Service National Refuge System. To protect human safety many areas are closed to access, although Cayo La Chiva in Vieques will be opened to public access following completion of the cleanup. Although environmental clean-up has been on-going and slow, social discontentment remains strong. Cleaning-up potentially live munitions requires acre by acre forest removal. To date, reforestation has been lacking, such that “cleaned” areas tend to be quickly colonized by invasive plant and vertebrate species. Management of vertebrate invasive species has also been largely lacking. Thus, although from a conservation perspective these lands are under protected status with reduced human access (due to safety risks), the ecological value of these lands is compromised due to the impacts of invasive species. Military activity on Monito and Desecheo Islands off the west coast devastated seabird colonies; these islands remain off limits to humans due to the risks associated with unexploded ordnance.

Climate Change Effects

Cays are at risk from climate change due to drought, rising sea levels, more intense and frequent storms, and potential natural and anthropogenic limits to inward (upslope) migration (Powell et al. 2017; Costanza et al., 2016). The resources on cays are sensitive to these influences because of the relatively small area and typically unique species assemblages. The most recent downscaled climate projections (Bowden et al. 2018; Gould et al., 2018) suggest changes in regional precipitation patterns and specifically longer and more intense droughts by mid-century (see also Murry et al., 2019 for coastal wetlands). Many organisms are adapted for xeric conditions, however extended drought, combined with increasing sea levels, storm surges, saltwater intrusion, and increased sea spray readily impacts native vegetation, paving the way for robust invasive species or loss of vegetation, with subsequent habitat-related impacts to native fauna.

Cays within the US Caribbean are not static features in time and space but change in shape, habitat, and ecological value in response to sea level, waves, currents, hurricanes, sediment inputs, and invasive species. Bush et al. (2014) provided an evaluation of historical shoreline change for a few of the cays around Puerto Rico. It is important to understand both global sea level trends, as well as local trends. Local tide gauges provide better estimates of sea level rise, and thus better insights into the long-term vulnerability of cays in response to local conditions, that we use to analyze low profile cays and their respective biological systems or habitats. Regardless, the vulnerability of cays is dependent on the ability of their elevation and habitats to keep pace with rates of sea level rise. For example, cays located in regions of tectonic uplift or subsidence can potentially minimize or exacerbate the impacts of long-term global sea level rise. Local, or relative, sea level rise rates do not necessarily match those of eustatic global dynamics.

Physical damage to the structure and transport of the loose or cemented coral carbonate skeletons is likely to increase due to stronger or more frequent hurricanes coupled with low rates of coral growth due to coral mortality and the net eroding effect of

increased ocean acidification. These erosion processes especially impact sand and coral cays. The physical action of the waves during high energy events such as hurricanes, storms, and swells increase substrates for coral re-colonization and coral fragmentation and redistribute coral rubble to low-lying areas creating space for islands to grow. These extreme events can also cause a high transport of sediments causing burial of benthic substrates and transporting material from shallow to deeper areas or vice versa. It has been suggested that reefs periodically disturbed by storms of intermediate intensity will increase growth rates and long-term calcification (Highsmith et al., 1980). However, it is certain that the ocean acidification caused by anthropogenic activities will increase in accord with atmospheric CO₂ emissions. Ocean acidification decreases the availability of the carbonate ion, CO₃²⁻ (the principal building block of most marine skeletal material), adversely affecting calcification and increasing dissolution processes. This leads to slow growth rates and malformed and less dense carbonate shells and skeletons (Cohen et al., 2009). As a result, species that undergo calcification may become displaced by species that do not. This will likely continue deteriorating reef conditions and cause ecological regime shifts from coral to algal reefs (Anthony et al., 2011). A decline in calcifying species (e.g., corals, crustose coralline algae, calcareous green algae) will affect the sediment budget available to island's shores, increase the potential for shore erosion, decrease the potential for carbonate island formation, and decrease beach and reef-based tourism and economic activity.

The combination of physical erosion, dissolution, and bioerosion processes in shallow reef habitats accelerate the loss of calcium carbonate sediments and decrease the stability of the reef skeletal framework (Eyre et al., 2014), potentially leading to a collapse of reef structures (Hoegh-Guldberg et al., 2007). Future acidification effects will not act independently from other global and local environmental pressures such as sedimentation. Such effects could compromise reef resiliency and increase vulnerability of certain types of islands in the face of other acute threats, such as thermal-stress, outbreak diseases, and rising sea level (Silverman et al., 2009).

It is estimated that coral reefs reduce the wave energy by an average of 97% (Ferrario et al., 2014) with most of the energy being absorbed at the shallower point (reef crest). In order for coral reefs to continue to provide coastal protection to low lying keys, corals will need to grow upward rapidly enough to keep pace with the rising sea level (Sheppard et al. 2005). If upward growth and reef complexity decrease due to ocean acidification, the reef will slowly "sink" as water depth increases and the wave energy reaching the shores behind those reefs will increase (Alvarez-Filip et al. 2009; Sheppard et al. 2005). In the case of the islands described herein, this will make coastal areas increasingly more vulnerable to the action of waves and storm surge with associated effects on the tourism sector, fisheries, and coastal infrastructure (Table 1).

Cay ramparts associated with high wave energy reefs are almost completely composed of Elkhorn coral as noted previously (Williams et al., 1999). If the live Elkhorn colonies that are the source of cay ramparts disappear, cays will be impacted in two ways: (1) they will receive more direct wave energy that is not dampened by the live corals, and (2) they may eventually erode away if no new pieces of coral skeletons are available to maintain accretion processes. Skeletons of Elkhorn coral form loose plate ramparts up to 4.5 m above sea level on cays exposed to high wave energy (Hernandez-Avila et al., 1977). This may protect the cays from wave-generated erosion and allow coral rubble and sand to accumulate on the cay. These ramparts also serve an ecologically important function as nesting habitat for many seabirds (e.g., least tern *Sternula antillarum*, brown noddies *Anous stolidus*).

Elkhorn coral once formed dense, high profile, monospecific stands in shallow depths (1–5 m) of the fore-reef zone and was abundant throughout the tropical Western Atlantic. In the 1970s and 1980s, Elkhorn coral experienced precipitous declines in abundance throughout its range, estimated at greater than 97% loss (NMFS 2014; Schärer et al., 2008). Data suggest that the decline in Elkhorn coral populations throughout Puerto Rico is primarily the result of disease and predation (Nemeth et al., 2014). Other threats to corals such as elevated seawater temperatures, overfishing, pollution, and ocean acidification are credible and potentially significant impediments to recovery of this species. In the past, storm damaged thickets have regenerated between major storms and thus produce the skeletal coral materials to replenish the cay ramparts during subsequent storms (Williams et al., 1999). The Elkhorn coral thickets also absorbed routine wave energy and protected the cays. Elkhorn coral abundance has significantly reduced the coral's ability to replenish cays and protect them from wave energy.

Climate Change Vulnerability

Climate change impacts, such as sea-level rise, storm surges, and drought could lead to a reduction in the size and number of low-lying islands while others that are morphologically resilient are expected to persist. Because the main islands of the US Virgin Islands have an extensive human footprint, they have relatively low conservation value; as such, the surrounding, largely uninhabited cays have been a focus of conservation efforts for decades. In contrast, until recently, the evaluation of small cays around Puerto Rico, their description, and ecologic importance have not received the attention that they deserve. Except for coral reefs, cays developed on coral rubble, sand shoals, and mangrove patches have received less attention. However, it is recognized that sea level rise and associated impacts are expected to negatively impact the ecological, societal, and economic benefits cays provide. Therefore, assessing the response of cays' shorelines to these stressors is critical for developing sound coastal management and land use planning guidelines for small islands (Bush et al., 2014; see Box 3).

Understanding the vulnerability of coastal areas is critical as this is the area where multiple stressors have the greatest opportunity to converge and where the greatest vulnerabilities lie (Gould et al., 2018). Toward that end, members of our writing team participated in a Climate Adaptation workshop to begin conceiving a long-term regional cays management plan in recognition that the species of greatest conservation interest span many jurisdictional management boundaries and occupy cays that individually range from low to very high vulnerability (based mainly on elevation). For this exercise two primary drivers were considered in scenarios

Table 1 Vulnerability of specific classes of biological targets to two specific drivers: sea level rise and extended droughts.

Climate driver	Targets	Climate-related impacts and vulnerabilities			Non-climate stressors	Relative vulnerability
		Exposure ^a	Sensitivity ^b	Adaptive capacity ^c		
Sea level rise	Sandy beaches and dunes	Extreme: at impact front	Extreme: change to aquatic habitat	Low: depending on island topography and accretion; habitat migration limited	Human recreation/disturbance	High
	Coastal shrub	Extreme: at impact front	Moderate-extreme: reduction in suitable area and salt spray	Low-moderate: depending on island topography; habitat migration limited	Human recreation/disturbance; invasive species (e.g., goats)	Moderate-high
	Rocky shores	Extreme: at impact front	Low-moderate: sand accretion could change to beach	Low-moderate: depending on island topography and accretion; habitat migration limited	Limited	Low-moderate
	Seabirds	Moderate-extreme: depending on specific microhabitat use	Moderate: depending on degree of habitat specificity	High: ability to alter habitat use (e.g., move upslope) or change islands	Invasive species; human recreation/disturbance; open ocean conditions	Moderate
	Endemic lizards	Moderate-extreme: many islands are low-lying	High: reduction in habitat space	Low: inability to colonize new islands without human intervention	(prey abundance, plastics)	High
	Endemic plants	Moderate-extreme: depending on specific microhabitat use	Moderate-extreme: reduction in habitat space and salt spray	Low-moderate: depending on mode of seed dispersal and degree of habitat specificity		Moderate-High
Extended droughts	Sandy beaches and dunes	Low	Low: dune plant desiccation	High: limited impacts	Human recreation/disturbance	Low
	Coastal shrub	Moderate	Moderate: shrub zone plant desiccation	Moderate: seed banking, selection toward drought resistance	Human recreation/disturbance; invasive species (e.g., goats)	Moderate
	Rocky shores	Low	None	High: limited impacts	Limited	Low
	Seabirds	Low-moderate: may experience some habitat changes	Low-moderate: not dependent on rain and moisture, but may experience habitat changes	Moderate: flexible nesting behavior; ability to move to more suitable islands, but drought likely to be regional	Invasive species; human recreation/disturbance; open ocean conditions (prey abundance, plastics)	Low-moderate
	Endemic lizards	Moderate: may experience some habitat changes	Low-moderate: dry adapted, but may experience changes in habitat and prey availability	Low-moderate: Behavioral responses to dryness, habitat, and prey changes		Moderate
	Endemic plants	High: water dependent to varying degrees	Low (cactus) to high: will depend on physiology	Low-moderate: depending on physiology and seed dispersal and dormancy		Low-high

This is not intended to be exhaustive nor overtly specific, but to serve as an example of the thought processes involved in assessing climate vulnerabilities. More precise vulnerabilities can be identified when considering specific species. Consideration is also paid to non-climate stressors that may have additive or synergistic effects.

^aExposure is defined by Stein et al. (2014) as the amount of change in climate and associated impacts the target species or system is likely to experience.

^bSensitivity is related to the affect or response of a species or target system to specific changes in climate variables or secondary effects.

^cAdaptive capacity refers to a species or system's ability to accommodate or cope with climate-associated changes.

Modeled after materials derived from: Stein, B.A., Glick, P., Edelson, N., and Staudt, A. (eds.). (2014). *Climate-smart conservation: Putting adaptation principles into practice*. National Wildlife Federation, Washington, D.C.

that were deemed independent and potentially synergistic, sea level rise and drought (Table 1). Specific habitat and species targets were identified, and we assessed their respective (and specific) exposure, sensitivity, and adaptive potential to the climate-related drivers (defined in Table 1). Importantly, we also considered non-climate stressors that will inevitably affect the vulnerability of the targets. Invasive species represented the greatest current and future threat and will likely be exacerbated by climate related impacts. We found that habitats tended to be more vulnerable to sea level rise than to droughts and sandy beaches and dunes more vulnerable than rocky shorelines (Table 1). Target species (seabirds, nesting sea turtles, lizards, and native plants) tended to also show greater vulnerability to sea level rise (through loss of habitat and habitat changes) than to drought.

A key step in developing a climate-smart adaptation plan is visualizing and defining a suite of potential future scenarios (Stein et al., 2014). Comparing and contrasting two climate change related impacts, namely sea level rise and drought, postulates four

Box 3 Case Study: Habitat Vulnerability Assessment of Small Oceanic Cays of Puerto Rico and U.S. Virgin Islands

Previous research conducted by [Bush et al. \(2014\)](#) between 2010 and 2013 focused on the assessment of coastal vulnerability and forecasted shoreline changes and land loss by application of three methods: (1) the simple slope/retreat model based on existing estimates of rates of sea-level rise; (2) historical shoreline change using t-sheets, aerial photographs, LiDAR, and satellite imagery, and extrapolation of those changes into the future; and (3) a coastal vulnerability index (CVI). The first approach presumes that the dominant control on coastal regression is the offshore/onshore long profile of the area of interest and the second approach presupposes that the shoreline change trends of the recent past will continue. Based on [Bush et al. \(2014\)](#), reliable data is available for both approaches; however, a more broad-based prediction can be made by applying a CVI. The CVI approach has been highly used in the United States and Canada but was applied in Puerto Rico and USVI for the first time to small islands in 2010. [Bush et al. \(2014\)](#) also employed the recently developed AMBUR (Analyzing Moving Boundaries Using R) software with the hazard-vulnerability assessment tool (AMBUR-HVA) to assess shoreline vulnerability for cays using geologic/geomorphologic data ([Bush et al. 2014](#); [Jackson et al., 2012](#)) (**Fig. B3.1**).

Fig. B3.1 High resolution UAV imagery of Caribe Cay, Peñuelas, Puerto Rico and inset showing submerged colonies of the threatened Elkhorn coral *Acropora palmata* in the fore reef area. Credit: HJR Reefscaping.

Since 2014, the USFWS Coastal Program has supported the collection of ecological information at landscape and seascape scales for cays around Puerto Rico and the USVI. The purpose is to determine population and/or habitat metrics that are more effective in assessing the sustainability of species and their habitats and to develop species/habitat vulnerability models that may be linked to existing and widely used geophysical models. This information will be used to assess species'

vulnerability to coastal hazards (erosion, inundation, and coastal exposure), climate change effects, as well as the need for habitat restoration and/or enhancement, and to identify and implement best management strategies. This initiative will be providing managers critical information: potential habitat loss in the context of spatial (i.e., sea, shoreline, cays and/or inland), temporal (e.g., 1 year, 10 years, 50 years, 100 years), and severity (i.e., low, medium, high risk) of these hazards. When complete this project is expected to provide the basis for developing assessment methods that would potentially be widely applicable to many coastal settings in the Southeastern U.S. and the Caribbean.

A multi-agency effort was initiated to establish a baseline for determining the vulnerability to climate change of small oceanic cays in the U.S. Caribbean. In 2013, local and federal natural resources agencies in collaboration with academic, private, and non-governmental organizations defined a series of research questions and management concerns that should be addressed in priority areas of interest. These concerns refer mainly to the potential loss of important habitats and the impacts upon the biodiversity and threatened or endangered species, particularly in areas where the marine and terrestrial environments interact in dynamic ways. The multi-disciplinary team identified criteria to rank study areas and chose 16 cays for this study spanning waters of Puerto Rico and the US Virgin Islands.

An ecosystem-based approach was devised to collect data on the marine, coastal, and terrestrial environments, allowing for the compilation of detailed data on habitat characteristics and species' composition on each cay. This information will be analyzed to determine habitat connectivity, patterns of habitat use (nesting, breeding, feeding, etc.), the location of critical habitats, incidence of habitat loss, and potential impacts to species' distributions. Detailed aerial ortho-photo mosaics, visual censuses, and underwater surveys near the shorelines are being conducted to evaluate the vulnerability of cays to climate change (Fig. 6). Preliminary results revealed the distribution of critical habitats for several threatened and endangered species such as the Virgin Island tree boa, St. Croix ground lizard, elkhorn and staghorn coral, and mountainous star coral on and around the cays. Data suggest that in some areas (1) inundation, (2) erosion, and (3) changes in vegetation are impacting the habitat quality and stability of cays and that preliminary model output (AMBUR-HVA-Cays, <http://ambur.r-forge.r-project.org/>) suggests fetch or coastal openness to wind/wave exposure is also a major factor influencing vulnerability.

potential future scenarios (Fig. 9); ranging from minor impacts from minimal sea level and minor increases in drought (lower left) to large increases in sea level rise and extended severe droughts (upper right).

The scenarios allow managers to prepare for a range of future conditions and prioritize actions to facilitate system adaptation (Table 2). All of the scenarios are nested within warmer ocean and air temperatures and continuing threats from invasive species and the impacts of human uses. Under the scenario of lowest impacts (lower left) managers can anticipate minor coastal erosion and instead focus attention on human disturbance and invasive species, whereas at the opposite extreme (upper right) where droughts and sea level rise are both high, managers will need to face increased threats of fire, loss of habitat space, potentially loss of low-lying islands, and severe habitat modification. Each scenario demands a separate suite of management actions to maximize resource allocation on the most likely threats. In the worst-case scenario this may include translocation of rare species from low-lying cays to higher elevation cays, facilitating habitat migration, and reducing non-climate stressors and threats (Table 2).

In conclusion, we continue to gather data on species and habitat distributions as well as climate, human, and ecological threats. The main goal must remain the implementation of conservation initiatives aimed at higher elevation habitats and species resilience to safeguard the long-term existence of these globally unique ecosystems.

Fig. 9 Four potential future scenarios based on low to high sea level rise and small to large increase in drought.

Table 2 Potential management actions toward climate resilience on Caribbean cays.

<i>Conservation goal:</i> Maintain or increase the population of endemic and native species and their associated habitats in the offshore islands of the Puerto Rican Bank and St. Croix through the end of the century	
Key vulnerabilities: Sea level rise and droughts	
Proposed action	Linkage of action to climate change
Coastal zone restoration: sand dunes, forests, implement living shorelines, facilitate habitat migration	Habitat loss from rising sea levels and drought
Artificial/engineered structures: e.g., breeding platforms, islands, shading breeding areas, oyster bars, desalinization and irrigation	Addresses negative impacts of drought and habitat loss
Captive propagation and breeding programs: for population supplementation plus genetic diversity	Supports evolutionary potential and mortality associated with extreme events
Move populations: Translocations of vulnerable species populations to less vulnerable islands (higher and bigger), use of enclosures and supplemental feeding/care to improve success, improve seabird attraction techniques	Response to sea level rise and loss of islands and habitat loss from drought
Invasive species elimination and prevention: continue to improve and implement biosecurity measures and eradication	Reduction of non-climate stressors and exotics that may benefit from climate change
Improve seabird foraging success: fish aggregation devices (FADs) to congregate prey fish and protective fisheries regulations, e.g., nursery areas, no-take zones	Reduction of non-climate stressors
Restore degraded habitats: e.g., bombed islands, by using drought tolerant species	Non-climate stressors and drought response
Human dimensions: “adopt a skink” or “adopt an island” program, visitor centers and education with sacrificial populations for public interaction	Non-climate stressors
Restricted human use areas: controlled access beached, target priority areas; conservation easements and other incentives	Non-climate stressors and avoid climate-driven habitat loss

Acknowledgments

The authors wish to acknowledge the on-going efforts of the Puerto Rico Climate Change Council (PR-CCC) and specifically the 2016 Puerto Rico Climate Vulnerability Assessment where an earlier version of this work was published. Permission to republish the expanded version here was given by Ernesto Diaz, Director of the PR-CCC. We also acknowledge Martha Prada and Kurt Grove who participated in that original version. The findings and conclusions in this article are those of the authors and do not necessarily represent the views of the U.S. Fish and Wildlife Service.

Abstract

The Hawaiian archipelago consists of an expansive chain of islands situated almost in the center of the Pacific Ocean, formed by the northwest movement of the Pacific tectonic plate over a volcanic hotspot where magma rises through the earth's mantle until it erupts through the seafloor. These islands range from small atolls in the northwest of the archipelago, to high volcanic islands in the southeast of the archipelago. The Hawaiian archipelago has an abundant range of biomes due to extreme variations in elevation, and variations in wind and rain patterns, topography, substrate, and hydrology. The archipelago's remote location in the vast Pacific Ocean also contributes to its physical geography. Each island and atoll has unique physical and biological features. Here we focus on the physical features of the Hawaiian archipelago.

Geography

The Hawaiian archipelago is the most isolated landmass in the world: approximately 2390 miles (mi) (3846 kilometers (km)) from California and approximately 3850 mi (6196 km) from Japan. The entire archipelago consists of approximately 132 islands, including 8 larger, younger islands (the "main islands"—the islands of Hawai'i, Maui, Kaho'olawe, Moloka'i, Lāna'i, O'ahu, and Kaua'i), and numerous smaller islands, islets, atolls, reefs, and shoals, stretching 1603 mi (2580 km) on a southeast-northwest line across the middle of the Pacific Ocean, between 150°48' and 178°20'W longitude, and 18°56' to 28°22'N latitude (Juvik and Juvik, 1998, p. xiii; Walker, 1999, p. 21) (Fig. 1). The archipelago has the same general latitude as Hong Kong and Mexico City (Juvik and Juvik, 1998, p. xiii). More than 99% of the land area is concentrated within the eight main islands located in the southeastern quarter of the chain (Walker, 1999, p. 21).

Fig. 1 Map of the Hawaiian archipelago including the main and northwestern islands. Source: <https://www.papahānaumokuākea.gov/>.

Geology

The main Hawaiian islands consists of eight main islands (Fig. 1; first eight entries in Table 1) that are substantially younger and larger than the long chain of older, eroded islands and atolls referred to as the Northwestern Hawaiian islands (NWHI). All of these islands were formed as the Pacific plate passed over a volcanic upwelling or accumulation of magma located in a transition zone located west of Hawaii Island (Fig. 2). Most of the world's active volcanoes are located at the edges of tectonic plates, such as observed with the Pacific "ring of fire;" however, some volcanoes are formed when magma rises up through a tectonic plate (Skilbeck and Whitehead 1978, pp. 499; 501; Clague, 1998, p. 37). These mid-plate volcanic areas are referred to as volcanic "hotspots." The creation of the Hawaiian archipelago has occurred over the last approximately 40 million years and is an ongoing process (Clague, 1998, p. 37; Cao et al., 2011, pp. 1068–1067). The Pacific plate is currently moving northwestward at about 4 inches (in) (9 centimeters (cm)) per year (Clague, 1998, p. 38). Each island was formed from eruptions of one or more undersea shield volcanoes which eventually grew to thousands of feet above sea level. Most of the islands formed over several hundred thousand years with several million years passing before activity ended and the volcano became extinct (Clague, 1998, pp. 38–39) (Fig. 2). As the islands increase in age they are carried northwest on the continental plate away from the hotspot. Clague and Sherrod (2014, p. 97) eloquently wrote:

As the Pacific Plate of the Earth's lithosphere moves slowly northwestward over the Hawaiian hotspot, volcanoes are successively born above it, evolve as they drift away from it, and eventually die and subside beneath the ocean surface.

Table 1 Geological summary and general characteristics of the Hawaiian archipelago.

Island (south to north)	Features and attributes						
	Emergent area <i>mi</i> ² (<i>km</i> ²)	Highest elevation <i>ft</i> (<i>m</i>)	Highest point	Coral reef or Atoll area (if applicable) <i>ac</i> (<i>ha</i>) ^a	Volcanic activity	Population (2010–15)	Surface water features
Hawai'i	4028 (10,430)	13,803 (4207.2)	Mauna Kea	25,946 (10,500)	Active	185,079	Bogs, streams, rivers, wetlands
Maui	727.2 (1883)	10,023 (3055)	Haleakalā	25,452 (10,300)	Dormant	154,834	Bogs, streams, wetlands
Kaho'olawe	44.59 (115.5)	1483 (452)	Pu'u Moaulanui	1320 (3262)	No	0	Seeps only

^aFor the eight main islands, defined as "total coral reef and hard bottom" (BAE Systems, 2007); for the northwestern Hawaiian Islands, undefined (Juvik and Juvik, 1998, pp. 24; 304).

^bSize depicted in acres/hectares.

Currently located above the most active area of the hotspot, the island of Hawai'i is the youngest island in the chain and is still experiencing frequent, geologically-recent volcanic activity. Kilauea, the youngest of the island's five volcanoes, has been erupting continuously since 1983. Lō'ihi Seamount, located 3200 feet (ft) (975 meters (m)) below sea level and 19 mi (29 km) southeast of the coast of Hawai'i, is destined to emerge as a new island within the next 200,000 years (Clague, 1998, pp. 45–46). Located approximately 32 mi (51 km) from the hotspot toward the northwest lies Maui, the second oldest island. Essentially the entire eastern side of the island is composed of Halaekalā volcano, a dormant shield volcano. Although Halaekalā's last eruption was in 1790, its long eruption history and recent activity indicate it will erupt again in the future (U.S. Geological Survey 2018 'Volcano Hazards Program' <https://volcanoes.usgs.gov/volcanoes/haleakala/>).

Substratum

The soils of the Hawaiian archipelago originate as basaltic lavas characterized by relatively low levels of silica, but rich in iron, magnesia, and lime (compared to substrates in other volcanic regions). Mueller-Dombois and Fosberg (1998, p. 472) divided Hawai'i soils into three broad classes: (a) undeveloped or geomorphologically recent soil substrates, (b) well-developed soils in humid climates, and (c) well-developed soils in seasonal or dry climates. Armstrong (1983, p. 45) attributes the variety of soils to differences in: (1) the length of time to which they have been exposed to weathering, (2) the materials from which they have formed, (3) drainage conditions, (4) the variety and abundance of plants and animals that live in and on them, and (5) rainfall and temperature conditions to which the soils are exposed (Armstrong, 1983, p. 45). The soils in Hawai'i weather relatively quickly due to the year-round warm temperatures resulting from the tropical climate (Juvik and Juvik, 1998, pp. 92–93).

Climate

Climate in the Hawaiian archipelago is characterized by mild and equable temperatures year-round (Fig. 3), low to moderate humidity, persistence of northeasterly trade winds, phenomenal differences in rainfall within short distances, and infrequent hurricanes and severe storms (Wagner et al., 1999, p. 36). Most areas in the Hawaiian archipelago experience only two seasons. Warmer and drier "summer" weather occurs primarily between May and September, when the sun is more or less directly overhead and the trade winds most persistent (Giambelluca and Schroeder, 1998, p. 49; Wagner et al., 1999, p. 36). Slightly cooler and wetter "winter" weather occurs primarily between October and April, when the sun is in the south and the trade winds are often interrupted by other winds and by intervals of widespread cloud cover and rainfall (Mueller-Dombois and Fosberg, 1998, p. 464; Wagner et al., 1999, p. 36). However, winter blizzards, ice, and snow are not uncommon on the arid high-elevation peaks of the volcanoes Mauna Kea and Mauna Loa on the island of Hawai'i, and Haleakalā on the island of Maui.

Hawai'i's steep and rugged mountains significantly influence its weather and climate (Mueller-Dombois and Fosberg, 1998, p. 464). The tremendous variety of peaks, valleys, ridges, and broad slopes, provides Hawai'i with a climate greatly different from the surrounding ocean as well as nearly innumerable micro-climatic variety within the islands (Giambelluca and Schroeder, 1998, p. 54; Wagner et al., 1999, pp. 37; 43). Depending upon their elevation, the mountains obstruct, deflect, and accelerate the flow of air, and due to a low inversion layer and moisture-laden trade winds, create a rainfall pattern known as orographic effect that produces predictable and substantial precipitation on several of the main islands (Figs. 4–6). The orographic effects occur when warm, moist air encounters steep ridges and mountains, rises, then cools as it reaches the inversion layer forming clouds and rainfall. Conversely, the

Geological Survey geologic investigations series map I-2800 (<https://pubs.usgs.gov/imap/2800>).

Fig. 3 Mean annual air temperature across the main Hawaiian islands (excluding Niihau). Source: Giambelluca, T.W., X. Shuai, M.L. Barnes, R.J. Alliss, R.J. Longman, T. Miura, Q. Chen, A.G. Frazier, R.G. Mudd, L. Cuo, and A.D. Businger. (2014). *Evapotranspiration of Hawai'i*. Final report submitted to the U.S. Army Corps of Engineers—Honolulu District, and the Commission on Water Resource Management, State of Hawai'i.

Fig. 4 This figure shows moist trade winds blowing toward and being forced upward on an island with a mountain that rises in elevation above the inversion layer. The rising air cools and condenses into rainfall which falls on the windward side of an island below the inversion layer (this example is similar to the specific orographic effects observed on the island of Hawai'i).

surrounding lowland and leeward areas tend to be sunny and dry. Air above the inversion layer warms again creating arid environment at high elevations (i.e., Mauna Kea, Mauna Loa, and Haleakalā). In places sheltered by terrain, local air movements are significantly different from winds in exposed localities, adding to the complexity and abundance of micro-climates. Since temperature decreases with elevation by about three degrees per one-thousand feet, Hawai'i's mountains, which extend from sea level to nearly 14,000 ft. (4267 m), contain a climatic range from the tropic to the sub-Arctic (Price, 1983, p. 59–61; Juvik and Juvik, 1998, pp. 121–127).

Rainfall

Annual mean rainfall ranges from 8 in (204 millimeters (mm)) near the dry, alpine summit of Mauna Kea to 400+ in (10,271+ mm) on the windward slopes of the tallest mountains on Kaua'i and Maui (Giambelluca et al., 2013, pp. 313–316) (Fig. 7). Comparatively, the surrounding ocean and most lowland areas of the islands receive an average of 20 in (500 mm)

Fig. 5 This figure shows moist trade winds blowing toward an island with a mountain that rises gradually in elevation below the inversion layer. In this case where the mountain summit is below the level of the inversion layer, it receives a maximum amount of rainfall, which falls on both the leeward and windward sides of the summit (this example is similar to the specific orographic effects observed on the island of Maui.).

Fig. 6 This figure shows moist trade winds blowing toward an island with a mountain that rises steeply and abruptly in elevation below the inversion layer. When trade winds are confronted by a steep cliff such as in this example, they rise upward rapidly, with the larger amount of rainfall occurring on the leeward side of the summit (this example is similar to the specific orographic effects observed on the windward side of the islands of Moloka'i and O'ahu.).

annually. As noted above ([Fig. 4](#)), this variability is created principally by orographic rainfall. When the moisture-laden trade winds encounter the high-elevation Hawaiian islands, they are forced to either pass around the mountain or rise up above it. As trade winds rise up the volcanic peaks, or remnants thereof, the air cools causing its water vapor to condense into visible clouds, and under persistent rising and cooling conditions, rainfall ([Wagner et al., 1999, p. 40](#)). The trade wind inversion creates a ceiling-like phenomenon that inhibits the further rising of the moist, warm air causing an accumulation of clouds and rain below it, and dry conditions above it ([Giambelluca and Schroeder, 1998, p. 53](#)). During the daytime and summer months, the tops of the higher Hawaiian mountains are almost constantly obscured by a band of clouds produced in this fashion ([Wagner et al., 1999, p. 38](#)). Persistent conditions promoting or inhibiting rising air are responsible for many of the differences in climate across the Hawaiian islands ([Giambelluca and Schroeder, 1998, p. 52](#)).

Trade Winds and Kona Storms

The Hawaiian archipelago experiences relatively consistent northeasterly trade winds throughout the year that originate from the North Pacific anticyclone, located northeast of the islands ([Giambelluca and Schroeder, 1998, p. 53](#)). However, the trade winds are more persistent in summer than in winter (frequencies average 90% and 50% respectively), and stronger in the afternoon than at night ([Wagner et al., 1999, p. 38](#)). They may blow continuously for long periods of time, particularly in the summer, but at times they remain absent for weeks ([Giambelluca and Schroeder, 1998, p. 53](#); [Wagner et al., 1999, p. 38](#)). Between October and April, Hawai'i may come under the influence of another type of low-pressure system that develops in the subtropics at high

Fig. 7 Mean annual rainfall across the main Hawaiian islands (excluding Ni'ihau). Source: Giambelluca, T.W., Q. Chen, A.G. Frazier, J.P. Price, Y.-L. Chen, P.-S. Chu, J.K. Eischeid, and D.M. Delparte. (2013). Online rainfall atlas of Hawai'i. *Bulletin of the American Meteorological Society* 94, 313–316, <https://doi.org/10.1175/BAMS-D-11-00228.1>.

altitudes and gradually extends toward the surface, sometimes forming west of Hawai'i (Giambelluca and Schroeder, 1998, p. 53). This type of system brings moist, southerly winds and rain, what is termed Kona storms (Kona meaning "leeward") (Giambelluca and Schroeder, 1998, p. 53; Mueller-Dombois and Fosberg, 1998, p. 466; Wagner et al., 1999, p. 38) (Fig. 8). Occasionally, the islands receive southwesterly winds preceding strong northerly winds that follow cold fronts. In the absence of trade winds and Kona storms, winds may be light or variable which results in ocean-land temperature and pressure differences that generate local diurnal variations in wind (Giambelluca and Schroeder, 1998, 59; Wagner et al., 1999, p. 38). Such diurnal heating and cooling of islands results in onshore sea breezes during the day and offshore land breezes at night (Wagner et al., 1999, p. 38).

Hydrology

In addition to rainfall, the primary factor driving the complexity and diversity of hydrological conditions observed in Hawai'i is the highly permeable nature of the islands' volcanic substrates, an attribute particularly prevalent on the younger islands of Hawai'i and

Fig. 8 Trade and Kona wind patterns on the island of Hawai'i. Modified from U.S. Geological Survey; map base layers from ESRI. "World Elevation3D/Terrain3D" [basemap]. Scale not given. "Terrain 3D". Maui (Juvik and Juvik, 1998, p. 89). To illustrate, the southern half of the island of Hawai'i from Hilo to Kohala lacks a single stream or river which reaches the coastline, over 220 mi (354 km) in all, despite some upslope areas receiving hundreds of inches of rainfall annually (Stearns, 1985, p. 291). However, substrate permeability varies considerably and in some rift zones of the mountains of the main islands, very hard, dense, and highly impermeable dike rock formations capture and hold large volumes of groundwater. This trapped groundwater slowly percolates through the rock horizontally toward areas of greater permeability including geologic faults and down-thrusts, or where rivers have carved channels through the dike formations (Stearns, 1985, pp. 294–298; Carlquist, 1992, p. 59; Polhemus, 2007, pp. 238–240).

Hawaiian Archipelago: Island Descriptions

Hawai'i

The island of Hawai'i, the largest, highest, and youngest of the main Hawaiian islands, is also the easternmost and southernmost island in the chain. It is located approximately 32 mi (51 km) from its nearest neighboring island, Maui. At 4038 square miles (mi²) (10,458 square kilometers (km²)), it comprises approximately two-thirds of the land area of the State of Hawai'i, making it Hawai'i's largest island, giving rise to its common name, the "Big Island." Five large shield volcanoes compose the island: Mauna Kea at 13,796 feet (ft) (4205 m) and Kohala at 5480 ft. (1670 m), both extinct, post shield stage, volcanoes; Hualalai at 8270 ft. (2520 m), the third most active volcano in the archipelago; and Mauna Loa (13,677 ft. (4169 m)) and Kilauea (4093 ft. (1248 m)), the second and first most active volcanoes in the archipelago, respectively (McDonald et al., 1990, pp. 345–379; USFWS 1994 (59 FR 10305, 1994); U.S. Geological Survey 2018 "Volcano Hazards Program" <https://volcanoes.usgs.gov>; Rubin 2018 "Hawaii Center for Volcanology" <http://www.soest.hawaii.edu/GG/hcv.html>). The island of Hawai'i includes a greater range of climatic zones than any other island in the State, with the highest and lowest temperatures, and several ecosystems ranging from coastal to alpine (Juvik and Juvik, 1998, p. 22; Wagner et al., 1999, p. 38, The Nature Conservancy of Hawai'i (TNCH) 2007 "Hawai'i High Islands" <http://www.hawaiieregionplan.info/>). The windward slopes receive the most rainfall, but orographic effects cause drier conditions to prevail in the leeward saddle area and in high elevation areas. The west or "leeward" side of the island (Kona), is in the rain shadow of the mountains, but does receive convection-driven rainfall in the afternoons resulting in annual rainfall ranging between 50 and 100 in (1270–2540 mm), capable of supporting mesic forest (Mitchell et al., 2005, pp. 6-71–6-91; Hawai'i Department of Land and Natural Resources, 2015, pp. 6-83–6-101).

Maui-Nui

The islands of Maui-Nui include Moloka'i, Lāna'i, Maui, and Kaho'olawe. During the last Ice Age about 21,000 years ago when sea levels were approximately 459 feet (ft) (140 meters (m)) below their present level, these four islands were connected by a broad lowland plain and unified as a single island (Nullet et al., 1998, p. 64; Ziegler, 2002, p. 22).

Maui Nui: Maui

The island of Maui (729 mi² (1888 km²)) is the second largest of the main Hawaiian islands (Juvik and Juvik, 1998, p. 14), and is located 32 mi (51 km) northwest of Hawai'i and 8 mi (13 km) from its nearest neighbor island, Kaho'olawe. Maui arose from two shield volcanoes resulting in formation of the west Maui mountains, which are about 1.3 million years old, and the east Maui mountains (Haleakalā volcano), about 750,000 years old (Juvik and Juvik, 1998, p. 14). These two mountain ranges are connected by the central Maui isthmus. The highest point on west Maui is Pu'u Kukui at 5788 ft. (1764 m) which receives 400 in (10,160 mm) rainfall per year (Juvik and Juvik, 1998, p. 14; Wagner et al., 1999, p. 41). East Maui's Haleakalā volcano last erupted only 200 years ago and is considered dormant (Juvik and Juvik, 1998, p. 14). Higher in elevation (10,023 ft. (3055 m)), Haleakalā is geologically younger and lacks the diverse vegetation of the older west Maui mountains. Annual rainfall on Haleakalā is about 35 in (890 mm) at the highest elevations, above the trade wind inversion, resulting in a dry cinder desert at the higher elevations (Giambelluca and Schroeder in Juvik and Juvik, 1998, p. 55). Lower elevations on windward east Maui receive as much as 404 in (10,262 mm) of annual rainfall (Giambelluca et al., 2013, p. 1).

Maui Nui: Kaho'olawe

Located 8 mi (13 km) southwest of the island of Maui, Kaho'olawe (45 mi² (116 km²)) is the smallest of the main Hawaiian islands and formed from a single shield volcano (Clague in Juvik and Juvik, 1998, p. 42; Juvik and Juvik, 1998, pp. 7–16). Its maximum elevation is 1476 ft. (450 m) at the summit of Pu'u 'O Moa'ula Nui (Juvik and Juvik, 1998, pp. 15–16). Because Kaho'olawe is located in the rain shadow of Haleakalā and is too low in elevation to experience orographic rainfall, it is relatively arid, receiving no more than 25 in (635 mm) of rainfall annually (Juvik and Juvik, 1998, p. 16; Mitchell et al., 2005, pp. 6–66).

Maui Nui: Lāna'i

Located 10 mi (17 km) south of Moloka'i and 9 mi (16 km) west of Maui, the island of Lāna'i (140 mi² (364 km²)) is the sixth largest of the main Hawaiian islands. Formed from a single shield volcano, its highest elevation is Lāna'ihale at 3366 ft. (1027 m). Due in part to a rain shadow cast by the west Maui mountains (Clague, 1998, p. 42), annual rainfall on the summit

ranges between 30 and 40 in (762 and 1016 mm). Annual rainfall is much less, ranging between 10 and 20 in (254 and 508 mm) over the lower elevation portions of the island (Giambelluca and Schroeder, 1998, p. 56).

Maui Nui: Moloka'i

Located 10 mi (17 km) north of Lāna'i and 10 mi (17 km) northwest of Maui, the island of Moloka'i (260 mi² (673 km²)), is the fifth largest of the main Hawaiian islands. The island is formed from three shield volcanoes, resulting in the east and west Moloka'i mountains and the Kalaupapa Peninsula (Juvik and Juvik, 1998, pp. 11–13). The taller and larger east Moloka'i mountain rises 4970 ft. (1514 m) above sea level and comprises roughly 50% of the island's area (Juvik and Juvik, 1998, pp. 11). Precipitous cliffs line the windward coast and deep valleys dissect the southern coastline. Annual rainfall on the windward side of the island ranges between 75 and 150 in (1905 and 3810 mm) (Giambelluca and Schroeder, 1998, p. 50). In contrast, the lower elevation, plain-like western half of the island is characterized by flat, rolling terrain that receives annual rainfall ranging between 15 and 30 in (381 and 762 mm).

O'ahu

Located 28 mi (46 km) west of Moloka'i, the island of O'ahu (600 mi² (1557 km²)) is the third oldest, third largest, and most populated of the main Hawaiian islands (Foote et al., 1972, p. 19; Juvik and Juvik, 1998, p. 7). The island is composed of two mountain ranges, the western Wai'anae range and the eastern Ko'olau range with a central plateau connecting them. These two mountain ranges formed from two separate shield volcanoes that ceased volcanic activity sometime between 1 and 2 million years ago. These mountain ranges are oriented perpendicular to the trade winds, creating distinctive leeward and windward climates due to the orographic effect. The arid Wai'anae range is located in the rain shadow of the Ko'olau range which receives most of the orographic rainfall (Juvik and Juvik, 1998, p. 7; Wagner et al., 1999, p. 39). The highest elevation on O'ahu occurs at the Mt. Ka'ala summit in the Wai'anae mountains (4025 ft., 1225 m) (Wagner et al., 1999, pp. 39–41). Rainfall on the island ranges from less than 20 in (500 mm) to more than 250 in (6350 mm) per year.

Kaua'i

Located approximately 76 mi (122 km) northwest of O'ahu, the island of Kaua'i (552 mi² (1430 km²)) is the oldest and northernmost of the main Hawaiian islands (Foote et al., 1972, p. 3). Kaua'i's highest elevation is Kawaikini Peak at 5148 ft. (1569 m), and the island's summit region is one of the most consistently wet areas on earth, receiving over 400 in (10,160 mm) of annual rainfall. Over 5 million years in age, erosion has created dramatic canyons and valleys across the island, notably Waimea Canyon and the rugged cliff lines on the Nā Pali Coast. In the past, Kaua'i has been severely affected by hurricanes, most recently by Hurricane Iniki in 1992 (U.S. Department of Commerce, 1993).

Ni'ihau

The island of Ni'ihau (69.5 mi² (180 km²)) is slightly younger than, and located 19 mi (31 km) southwest of, Kaua'i. Formed from a single shield volcano, it has unique geographic features including a low, flat plain with intermittent lakes. Ni'ihau is relatively arid, receiving 20–40 in (508–1016 mm) of annual rainfall, because it lies in the rain shadow of Kaua'i and lacks the elevation needed to create orographic rainfall (Stearns and MacDonald, 1947, p. 31). However, Kona storms provide some rainfall during the season of Kona winds. Although only 1280 ft. (390 m) at its highest elevation, Ni'ihau's northern coast includes precipitous sea cliffs. The geologically-related, but separate islet, of Lehua Island is a crescent-shaped tuff (ash) cone 284 ac (115 ha), that lies 0.7 mi (1.1 km) north of Ni'ihau, (Juvik and Juvik, 1998, pp. 3–6). Ka'ula Island 158 ac (64 ha), also known as Ka'ula Rock, is a small, crescent-shaped tuff cone, 550 ft. (167 m) high, and lies southwest of Ni'ihau.

Northwestern Hawaiian Islands

The Northwestern Hawaiian islands are located northwest of the inhabited main Hawaiian islands and consist of ten islands and atolls that span approximately 1200 mi (2000 km) beginning with the island of Nihoa to the southeast and extending to Kure atoll at the northwestern end. The islands were formed approximately 7–30 million years ago, as tall shield volcanoes over the same volcanic hotspot that formed the Emperor seamounts to the north and the main Hawaiian islands to the south (Clague and Dalrymple, 1989, p. 5). As the Pacific Plate moved north and later northwest over the hot spot, volcanic eruptions built up islands in a linear chain. The isolated land masses gradually eroded and subsided, beginning as high islands in the south, to become small atolls and seamounts north of 29°N Latitude (Fig. 1). In various stages of erosion, the Northwestern Hawaiian islands include an evolution from rocky basaltic islands surrounded by atolls or reefs such as Nihoa, Mokumanamana (Necker), Ōnūnui (Gardner Pinnacles), and Lalo (French Frigate Shoals), to the low sandy islands and atolls found to the north, including Kamole (Laysan), Kapou (Lisianski), Manawai (Pearl and Hermes), Kuaihelani (Midway), and Hōlanikū (Kure Atoll). Beyond Hōlanikū (Kure Atoll), the islands have completely subsided as the plate carries them forward into waters too cool for the formation of coral reefs to keep pace with the natural subsidence and erosion process (Fig. 9).

An important aspect of the Hawaiian cultural revival is the awareness that in numerous instances traditional place names either were replaced with foreign names or the Hawaiian names were misspelled to the degree that their meanings were changed.

Fig. 9 How Volcanic Islands change to Atolls over time.

Consequently, the Hawaiian Lexicon Committee first published names for the NWHI in 1998, and then again in 2007. The new official name of Papahānaumokuākea was chosen to denote all of the northwestern islands and atolls. [Kikiloi \(2010, entire\)](#), updated the Hawaiian names for the NWHI based on 19th century Hawaiian language documents which we include here ([Table 2](#)).

Nihoa

Located 150 mi (240 km) northwest of the island of Kauaʻi, Nihoa is the tallest of 10 islands and atolls in the NWHI and is 0.27 mi² (0.6 km²) in land area ([Juvik and Juvik, 1998, pp. 24; 304](#)). The island has two peaks, Miller's Peak (892 ft. (272 m)) in the west and Tanager Peak (850 ft. (259 m)) in the east. The surface of the island slopes southward with an average decline of 23°. Although there are no permanent streams on the island, ephemeral streams have carved six major south flowing drainage valleys across the island. Hydrology includes three small water seeps, all located at the bottom of drainage valleys ([Evenhuis and Eldredge, 2004, pp. 27–28](#)).

Mokumanamana (Necker Island)

Located approximately 155 mi (249 km) northwest of Nihoa and lying north of the Tropic of Cancer, Necker is approximately 0.06 mi² (0.16 km²) in land area ([Juvik and Juvik, 1998, pp. 24; 304](#)). Composed of small peaks and intervening swales, Necker is the last

Table 2 List of known Hawaiian names for the Northwestern Hawaiian Islands^a

remnants of an old, stream-eroded basaltic island. The edges of its individual islets are defined by steep sea cliffs with bases featuring wave-cut benches a few meters above sea level. Hydrology includes a few small seeps (Evenhuis and Eldredge, 2004, pp. 30–31).

Kānemiloha'i (French Frigate Shoals)

Located approximately 85 mi (137 km) northwest of Necker Island, French Frigate Shoals is the largest atoll in the NWHI in the form of an 18 mi (28.9 km) long crescent (Juvik and Juvik, 1998, pp. 24; 304). An estimated 12.3 million years old (Clague, 1998, p. 38), the shoals consist of 67 acres (0.27 km²) of total emergent rocky pinnacle and sand islands surrounded by approximately 230,000 acres (931 km²) of coral reef habitat. A combination of sand, rubble, nonliving coral substrate, and crustose coral-line algae occurs in the windward and exposed lagoon areas. The lagoon is unusual in that it contains two exposed volcanic pinnacles representing the last vestiges of the high island from which the atoll developed. The three small sand islets continually change size, shift position or disappear and reappear.

Pūhāhonu (Gardner Pinnacles)

Located approximately 108 mi (174 km) northwest of French Frigate Shoals, Gardner Pinnacles is the northernmost island in the chain with emergent portions of volcanic origin. These two basaltic peaks estimated at 15.8 million years in age (Clague, 1998, p. 38) are similar in size to the pinnacles of French Frigate Shoals, measuring approximately 180 feet (54.8 m) in height with a diameter of 590 ft. (179.8 m) (Juvik and Juvik, 1998, pp. 24; 304). These remnant volcanic pinnacles are surrounded by approximately 600,000 acres (2428 km²) of coral reef, most of which is in waters 60 feet (18.3 m) or deeper.

Kō'anakō'a, Nalukākala (Maro Reef)

Located between Gardner Pinnacle and Laysan Island, Maro Reef is a largely submerged open atoll 19.7 million years in age (Clague, 1998, p. 38). Less than one acre (4046.8 m²) of land is emergent, when during very low tide, a small coral outcrop of a former island breaks the surface of the water. The shallow water reef system is extensive, covering nearly a half-million acres (2023 km²) (Juvik and Juvik, 1998, p. 24), making Maro the largest coral reef in the region. Because its outermost reefs absorb the majority of the energy from the open ocean swells, the innermost reticulated reefs and aggregated patch reefs are sheltered and exhibit several characteristics of a true lagoon.

Kauō (Laysan Island)

Located approximately 342 mi (550 km) northwest of Gardner Pinnacles, Laysan is a raised atoll estimated at 20.7 million years in age (Clague, 1998, p. 38). With a maximum elevation of approximately 50 ft. (15 m) above sea level, it has a land area of approximately 1023 acres (4.14 km²), surrounded by 100,000 acres (405 km²) of coral reef (Juvik and Juvik, 1998, pp. 24; 304). Most of the reef lies in deeper waters with a small, shallow-water reef area in a bay off the southwest side of the island. Laysan's ring of sandy dunes surround a shallow depression of about 200 acres (0.8 km²) that contains a mix of hypersaline water and mud flats, a feature unique within the Hawaiian Archipelago and rare within the Pacific region. This hypersaline lake changes in size depending on variations in rainfall.

Lisianski (Papa'āpoho) and Neva Shoal

Located approximately 112 mi (180 km) northwest of Laysan, Lisianski Island is another raised atoll, estimated at 23.4-million years in age (Clague, 1998, p. 38). Rising to 40 ft. (12.1 m) above sea level, it includes approximately 400 acres (1.6 km²) of emergent land (Juvik and Juvik, 1998, pp. 24; 304). This island measures approximately 1.2 miles (1.9 km) in width and consists of an elevated rim surrounding a broad central depression, which unlike Laysan, does not enclose an interior saline lake. An extensive platform-like coral reef, called Neva Shoals, surrounds the island and totals more than 290,000 acres (1.74 km²). This reef covers approximately 60% of the lagoon/atoll's substrate.

Holoikauaia (Pearl and Hermes Atoll)

Located approximately 257 mi (414 km) northwest of Lisianski, Pearl and Hermes Atoll is a large atoll with several small islets, forming 96 acres (0.38 km²) of emergent land surrounded by more than 300,000 acres (1214 km²) of coral reef (Juvik and Juvik, 1998, p. 304). Estimated at 26.8 million years in age (Clague, 1998, p. 38), the atoll is 20 miles (32 km) across and 12 miles (19.3 km) wide (Juvik and Juvik, 1998, p. 24). Unlike Lisianski and Laysan to the southeast, Pearl and Hermes Atoll is a true atoll, fringed with shoals, permanent emergent islands, and ephemeral sandy islets.

Pihemanu (Midway Atoll)

Located approximately 15 mi (24 km) northwest of Pearl and Hermes, Midway Atoll consists of three sandy islets totaling 1464 acres (5.9 km²) in terrestrial area and lying within a large, elliptical barrier reef measuring approximately 5 miles (8 km) in diameter. The three islets include, Sand measuring 1117 ac (4.56 km²), Eastern measuring 337 ac (1.36 km²), and Spit, measuring 13 ac (0.05 km²) (Juvik and Juvik, 1998, pp. 24; 304). Estimated at 28.7 million years in age (Clague, 1998, p. 38), the atoll is surrounded by more than 88,500 acres (356 km²) of coral reefs. Core samples taken by the U.S. Geological Survey found solid basaltic rock 180 ft (54.8 m) beneath Sand Island and 1240 ft (377.9 m) beneath the northern reef.

Mokupāpapa (Kure Atoll)

Located approximately 55 mi (89 km) northwest of Midway Atoll, Kure is the most northwestern island in the Hawaiian chain and occupies a singular position at the “Darwin Point,” which is the northern extent of coral reef development, beyond which coral growth cannot keep pace with the rate of geological subsidence (Grigg, 1982, p. 29). Estimated at 29.8 million years of age (Clague, 1998, p. 38), Kure Atoll is circular in shape, with a coral reef measuring approximately 6 mi (9.6 km) in diameter and enclosing a lagoon. Two islets consisting of over 200 ac (0.91 km²) of emergent land are flanked by almost 80,000 acres (324 km²) of coral reef within the lagoon (Juvik and Juvik, 1998, pp. 24; 304). An outer reef forms a nearly complete circular barrier around the lagoon, with the exception of passages to the southwest. Of the two enclosed islets, the only perennially permanent land is found on the crescent-shaped Green Island, which rises to 20 ft. (6.1 m) above sea level and is located near the fringing reef in the southeastern quadrant of the lagoon. Currently, The coral around Kure is still growing, slightly faster than the island is subsiding. North of Kure, where growth rates are even slower, the drowned Emperor Seamounts foretell the future of Kure and all of the Hawaiian Archipelago. As Kure Atoll continues its slow migration atop the Pacific Plate, it too will eventually slip below the surface.

Abstract

We provide an overview of the coastal ecosystem of the Hawaiian archipelago and describe the ecological factors that have influenced the ecosystem in the past, present, and future. Coastal ecosystems found throughout the Hawaiian archipelago are subject to oceanic influences such as winds, salt-spray, and wave energy. Two coastal ecosystem sub-types occur in the archipelago and are defined by moisture regime: coastal dry and coastal wet-mesic sub-types. Limited information exists about what coastal ecosystems and their associated ecological communities looked like prior to human-contact. The assumption is that coastal ecosystems were historically more resilient to stochastic events because they had more continuous populations of native flora with a higher faunal diversity. Currently, coastal ecosystems are in decline due to factors such as conversion pressure from expanding development and agriculture and the introduction of invasive species. We analyzed four scenarios for a foreseeable future of coastal ecosystems with varying levels of change in Conservation Management Parameters: conservation values, laws and biosecurity, and development or conservation planning. We anticipate that coastal ecosystems will continue to decline unless significant management change occurs.

Introduction

The Hawaiian archipelago in the Pacific Ocean is more than 3200 km from the nearest continental land mass with extreme variations in elevation, wind, rain, topography, substrate, and hydrology. These variations create unique ecosystems across the archipelago. We provide an overview of the coastal ecosystem in Hawai'i and describe the ecological factors that have influenced it over time. Please see the chapter on *Physical Geography of the Hawaiian Islands* for a full description of the unique geography, geology, climate, hydrology and descriptions of the islands in the Hawaiian archipelago.

Description

Defining Hawaiian Islands Coastal Ecosystems

Coastal ecosystems are defined as near-shore areas impacted by the ocean. Bound by ocean on one side, these ecosystems generally range within 100 m of the high tide, and up to 300 m in elevation. This limit is determined by the effect of seawater on the substratum and plant rooting zone; the limit of spray kill; and the limit of formations such as sand dunes, elevated coral outcrops, and marine terraces, which are created largely through shoreline processes (e.g., inundation or exposure to salt water and onshore flow of 'ehukai salt mist, strong winds, movement of sand by winds, and brackish basal groundwater; see [Richmond and Mueller-Dombois, 1972](#); [Gagné and Cuddihy, 1999](#); [Warshauer et al., 2009](#)) and sometimes extends farther inland if strong prevailing onshore winds drive these processes into the lowland zone ([TNCH, 2009](#)).

Coastal ecosystems are found on all of the main Hawaiian Islands (Hawai'i, Maui, Moloka'i, Kaho'olawe, Lāna'i, O'ahu, Kaua'i, and Ni'ihau) and offshore islets. The highest species diversity occurs in the least populated and undeveloped coastal areas on the main Hawaiian Islands. These ecosystems also occur on the islands and atolls within the islands in the Northwestern Hawaiian Islands (NWHI or Papahānaumokuākea).

The coastal substrate consists of well-drained talus (the pile of rocks that accumulate at the base of a cliff, chute, or slopes), calcareous (limestone) slopes, and dunes. This ecosystem can be dry (less than 1200 mm annual rainfall), mesic (1200–2500 mm), and wet (more than 2500 mm). The vegetation community within these dry and wet-mesic ecosystems consist of herblands, sedgelands, grasslands, shrublands, mixed communities, and forests ([Table 1](#) and described below).

Pre-human Condition

Information about native vegetation in Hawai'i prior to the arrival of humans is limited. Our assumptions are based on existing vegetation, remnants in disturbed areas, patterns of climate and substrates, and a few fossilized remains ([Cuddihy and Stone, 1990](#)). Coastal ecosystems were found on all islands in the archipelago in a continuous ring, only interrupted by stretches of recent lava flows or unstable cliff faces ([Jacobi and Warshauer, 2017](#)). Native flora and fauna existing today are likely remnants of larger, more extensive past populations of flora and fauna ([Gagné and Cuddihy, 1999](#)). What is now an island or atoll within the Northwestern Hawaiian Islands was likely a high elevation island with a varying array of vegetation communities that do not currently exist. For example, typical high island tree species such as loulou (*Pritchardia* sp.) and 'iliahī (sandalwood, *Santalum ellipticum*) on the coral island of Kamole (Laysan) might have been the remnant of a more expansive vegetation community present at one time on a higher elevation island form ([Mueller-Dombois and Fosberg, 1998](#)) ([Fig. 1](#)).

Vegetation on rocky shores were low growing and mat forming species in areas closest to the ocean ([Warshauer et al., 2009](#)), or stunted due to strong winds (e.g., tree species grew to shrub forms) ([Gagné and Cuddihy, 1999](#)). Taller plants grew farther inland or where accumulated soil was locally available ([Warshauer et al., 2009](#)). A range of conditions at other sites allowed for species diversity within coastal communities ([Warshauer et al., 2009](#)). We assume that healthy, functioning coastal ecosystems unaltered by humans had the ability to provide natural protective buffers for inland ecosystems ([Fig. 2](#)).

Dry Hawaiian coastal ecosystems historically occurred on all coral atolls and high island remnants of the NWHI, and along the coastlines of all the main islands ([Gagné and Cuddihy, 1999](#)). They were likely more extensive on the drier leeward sides of larger

Table 1 Categories and sub-units of Hawaiian coastal systems and dominant plant species and vegetation type were used to classify habitat sub-units based on their elevation and moisture regimes within the coastal boundaries.

Coastal communities

Fig. 2 Low growing and mat forming shrubs at Ka'ena Point on the island of O'ahu.

islands and on all sides of the smaller, arid islands and atolls in the Hawaiian archipelago (Gagné and Cuddihy, 1999; Landfire, 2016). Certain plants such as naupaka kahakai (*Scaevola taccada*) were able to utilize the brackish groundwater to grow year-round (Gagné and Cuddihy, 1999). Other typical coastal dry vegetation consisted of 'ōhai (*Sesbania tomentosa*), 'aki'a (*Wikstroemia uva-ursi*), naio (*Myoporum sandwicense*), pōpolo, 'akoko (*Chamaesyce celasroides*), 'ewa hinahina (*Achyranthes splendens* var. *rotundata*), pā'ū o Hi'iaka (*Jacquemontia ovalifolia* subsp. *sandwicensis*), and 'ilima (*Sida fallax*) (see Table 2) (Fig. 3).

Wet coastal ecosystems in Hawai'i included nutrient-rich flood plains, marshes, lowland riparian, fresh groundwater, and permanent stream areas. These included the coastal wet forests and the coastal mesic forests (see Table 3) (Fig. 4).

Hawaiian vertebrate species such as honu (Hawaiian green sea turtle, *Chelonia mydas*), honu 'ea (hawksbill turtle, *Eretmochelys imbricata*), and 'ilioholoholoikauaua (Hawaiian monk seal, *Monachus schauinslandi*) frequented coastlines where the offshore waters provide an abundance of limu and reef protection from predatory shark species. 'Ōpe'ape'a (Hawaiian hoary bat, *Lasiurus cinereus semotus*) foraged along the coasts searching for insect prey. Nesting seabirds left their young in sandy or rocky burrows to forage in the prey rich sources offshore. Other seabirds used the edge of the vegetation line to lay their eggs away from the high tide. Other native birds (e.g., finches (Family: Fringillidae), millerbirds (Family: Acrocephalidae), large flightless birds (Family: Anatidae), and various migratory shorebirds) used the native vegetation to build their nests and forage for food sources within the coastal

Table 2 Historic and current condition of coastal dry communities.

	Historic condition	Current condition
Coastal dry herblands	Coastal dry herblands occurred in rocky areas, on coralline surfaces, and on mudflats adjacent to lagoons, marshes, and anchialine pools on coralline or basaltic surfaces; from 0 to 5 m elevation; with an annual rainfall from less than 250 mm to more than 1000 mm (Gagné and Cuddihy, 1999). Dominant herb species included hinahina kahakai (<i>Nama sandwicensis</i>) and 'Akulikuli (<i>Sesuvium portulacastrum</i>) (Gagné and Cuddihy, 1999). Other herbaceous plants consisted of pā'ū o Hi'iaka and 'ohelo kai (<i>Lycium sandwicense</i>) (Gagné and Cuddihy, 1999).	Nama and 'akulikuli dry herbland communities currently occur only where human disturbance is minimized and along coastal bluffs and cliffs where there are rocky areas and coral surfaces (Gagné and Cuddihy, 1999, p. 55). Some of these native communities have been replaced by the non-native slender sea-purslane (<i>Sesuvium maritimum</i>).
Coastal dry grasslands	Coastal dry grasslands typically occurred in leeward areas, at sea level to 300 m elevation with an annual rainfall from 250 to 1000 mm, on variety of substrates of well-drained calcareous sand to newly vegetated volcanic flows (Gagné and Cuddihy, 1999). The plant communities were often subject to summer drought and "brown off" (with the exception of 'aki'aki (<i>Sporobolus virginicus</i>) and kāwelu (<i>Eragrostis variabilis</i>) (Gagné and Cuddihy, 1999). 'Aki'aki, kāwelu, and <i>Lepturus repens</i> were the dominant grasses.	Native coastal dry grasslands are limited to a few coastal dunes on which human disturbance has been minimized (Gagné and Cuddihy, 1999, p. 57). 'Aki'aki grasslands have been converted to kiawe forest communities. Nonnative weeds remain the primary threat to 'aki'aki, kāwelu, and <i>Lepturus</i> grassland communities (Gagné and Cuddihy, 1999, p. 58). 'Aki'aki is often the only native understory species beneath kiawe. Otherwise, the understories are dominated by nonnative drought-resistant grasses and herbs, particularly buffelgrass (<i>Cenchrus ciliaris</i>) fingergrass (<i>Chloris</i> spp.), and guinea grass.
Coastal dry mixed communities	Coastal dry mixed communities occurred on talus slopes or on shallow, rocky, weathered clay soils, especially in leeward areas with an annual rainfall of less than 500 mm, often subject to winter storm salt spray (Gagné and Cuddihy, 1999). 'Ilima was the dominant plant species.	'Ilima mixed shrub and grassland communities are still found, however, fingergrass now occurs with 'ilima as a dominant hybrid community in this coastal dry habitat. Additionally, in drier sites on the main Hawaiian Islands these communities have usually been replaced by kiawe, koa haole, Christmas berry or klu (<i>Acacia farnesiana</i>). Protection by isolation, especially from feral herbivores provides some protection to the native mixed community.
Coastal dry shrublands	Coastal dry shrubland communities occurred mostly on flat, rocky sites in open, widespread coastal areas below 300 m with an annual rainfall of less than 500 mm; small shrubs in this community were subject to harsh environmental conditions (e.g., highly seasonal precipitation, large temperature fluctuations, and intense solar radiation) (Gagné and Cuddihy, 1999). Naupaka kahakai (<i>Scaevola taccada</i>), 'ilima, ma'o, hinahina/kipūkai (<i>Heliotropium anomalum</i> var. <i>argenteum</i>)/ (<i>H. curassavicum</i>), and 'iliahialo'e (<i>Santalum ellipticum</i>) were dominant species. Coastal cliff mixed shrubland, another sub-habitat of the coastal dry shrublands, consisted of a mix of 'ilima, nehe (<i>Lipochaeta</i> spp.), 'akoko (<i>Euphorbia degeneri</i>), kāwelu, <i>Schiedea globosa</i> , and 'ānaunau (<i>Lepidium bidentatum</i> var. <i>o-waihiense</i>) species); 'Āweoweo (<i>Chenopodium oahuense</i>) and, pua kala (<i>Argemone glauca</i>), naio.	Native coastal dry shrubland communities occur where they are not subjected to grazing. Abandoned grazing lands along coastlines are extensive thickets of koa haole shrublands. Christmas berry and kiawe forest are also components of these shrublands, the latter community prevailing especially where kiawe is able to tap brackish groundwater. Currently predominantly native dry shrublands consist of mostly nonnatives. Naupaka kahakai shrubland occurring on dunes can be mixed with invasive species such as Indian fleabane (<i>Pluchea indica</i>), sourbush (<i>Pluchea carolinensis</i>) and Christmas berry; on raised coral can be found with stinking passionflower (<i>Passiflora foetida</i>); and on basalt cliffs can be found with sweet acacia (<i>Acacia farnesiana</i>). 'Ilima, ma'o, and hinahina/kipūkai, and 'a'ali'i shrublands occur on a few locations in the main Hawaiian Islands. Although severely disturbed by roads, trails, and nonnative weeds and only represented by a single natural occurrence at Makapu'u on O'ahu, 'iliahialo'e shrubland remains a native-dominated community (Gagné and Cuddihy, 1999). Coastal cliff mixed shrublands grade into nonnative dominated communities from the top to bottom of cliff bases. Native species are not large components of these communities.

Table 2 Historic and current condition of coastal dry communities.—cont'd

	Historic condition	Current condition
		Most of the native coastal dry shrublands that remain are being destroyed by urbanization, off-road vehicle activity, arson, grazing, and encroachment by nonnative plant species. 'Ilima, 'āweoweo, and naupaka kahakai shrublands occur on federally protected lands in the NWHI; naupaka kahakai shrublands are fairly dominant in certain coastal areas of the main Hawaiian Islands. Coastal cliff mixed shrublands also have some natural barriers (steepness of cliff slopes) which make it impossible for nonnative ungulates and predators to access, but is almost ubiquitously disturbed by nonnative plants. Although several of these communities occur within the State's Ka'ena Point Natural Area Reserve on O'ahu, they have not yet received protective management. Ma'o, hinahina/kipūkai, 'iliahialo'e, and naio shrub lands remain unprotected. The coastal dry shrubland is often delineated at the inland boundary by nonnative lowland shrubs and trees (klu, kiawe, koa haole, and Christmas berry) where the degree of salt spray, is minimal. No extant intact naio shrublands currently exist; only remnant scattered clumps of naio occur in the lowlands of O'ahu, such as on the Mokulē'ia side of Ka'ena Point, where they have not been impacted by agriculture or fire and subsequently replaced by nonnative shrublands or forests. On Laysan, this vegetational association was an important element until it was destroyed by introduced rabbits in the early 1900s and replaced by shrublands of Indian fleabane. 'Āweoweo coastal shrublands have since been reintroduced on Lisianski and Laysan.
Coastal dry forests	Coastal dry forests occurred in gently sloping and level lowlands, in areas where there was sufficient soil (Gagné and Cuddihy, 1999). Ground cover consisting of 'aki'aki extended inland beneath taller tree species such as wiliwili (<i>Erythrina sandwicensis</i>), 'ohe makai (<i>Reynoldsia sandwicensis</i>), and loulou (<i>Pritchardia</i> spp.). Typical plants in this community included 'ilima and nehe. Vegetation in the semi-arid conditions on the leeward coasts were able to utilize brackish water found under talus and alluvial substrates.	Additionally, wiliwili, 'ohe makai, and hoary abutilon have been replaced with invasive species such as lantana (<i>Lantana camara</i>), klu, Christmas berry, koa haole, or kiawe (the latter being the current dominant species in the coastal dry forest). Because kiawe is able to utilize brackish groundwater at great depths it thrives in the semi-arid conditions along this coastal habitat type. Logwood (<i>Haematoxylum campechianum</i>) is locally quite abundant and may be codominant with kiawe on the south Kona coast of Hawai'i Island.

Adapted from Gagné WC and Cuddihy LW (1999) Vegetation. In: Wagner WL, Herbst DR, and Sohmer SH (eds.) *Manual of the Flowering Plants of Hawai'i*, pp. 45–114. Honolulu: University of Hawai'i Press, Bishop Museum Press.

ecosystem. Native insects such as the yellow-faced bee (*Hylaeus* spp.) used the branches of native vegetation to build their nests. In short, these coastal areas were vibrant, diverse ecological communities that could sustain the ecological processes within the ecosystem.

Coastal Ecosystem Viability

We suspect that species viability in coastal ecosystems depended on maintaining multiple, distributed (or redundant) populations of sufficient quality and size to be resilient to change, and with a species richness and representative of a genetic range to survive across their ecological environment over time. The distribution of the coastal ecosystems in the Hawaiian archipelago likely provided the redundancy, which allowed the ecosystem to withstand stochastic events (like volcanic eruptions or hurricanes) on portions of the habitat.

We assume the ecosystem viability of coastal communities before pre-human contact were very resilient, redundant, and well represented and occurred in a continuous ring on all the islands, only restricted by elevation, rainfall, and ocean influences. Because they were widely distributed, it is believed their ability to recover from catastrophic events was more likely. These communities tolerated natural disturbances and any changes or variations to the environment.

Current Condition

Hawaiian coastal ecosystems have been transformed either intentionally (e.g., ornamental or food crops, human residences or hotels, other development such as harbors, jetties, and piers) or inadvertently (e.g., examples plus climate) by humans. Non-

Fig. 3 'Ōhai and naupaka on the island of O'ahu.

Table 3 Historic and current condition of coastal wet-mesic communities.

	<i>Historic condition</i>	<i>Current condition</i>
Coastal wet forests	Coastal wet forests were likely a widespread community which occurred on the windward coastlines (Gagné and Cuddihy, 1999). 'Ōhi'a (<i>Metrosideros polymorpha</i>) and lama (<i>Diospyros sandwicensis</i>) were likely widespread on the windward coasts (Gagné and Cuddihy, 1999).	'Ōhi'a/lama wet forests no longer exist as a primary dominant community type in the coastal habitat. The wet coastal forests that exist today are mangrove swamps consisting of American mangrove (<i>Rhizophora mangle</i>) and oriental mangrove (<i>Bruguiera gymnorhiza</i>).
Coastal mesic forests	Coastal mesic forests occurred on sandy coastlines, wetter lower slopes, valley bottoms, land shelves, and cliff bases from 0 to 493 ft. (150 m) elevation in areas with an annual rainfall of 71–150 in (1800–3800 mm) (Gagné and Cuddihy, 1999). Loulu were the dominant tree species in the coastal wet-mesic habitat.	Both hala and loulu coastal mesic forests are rare. Hala forests are now uncommon but still occur in areas not excessively altered by humans, e.g., example on the Nā Pali coast trail on the island of Kaua'i. Fairly intact hala forest are also found along the Puna coastline on Hawai'i Island but have since been covered by current (2018) lava flows. Only one extant population of loulu coastal forest currently remains on the island of Nihoa. This last loulu forest community is unique in that it is not subject to invasive mammalian seed predators. Common ironwood (<i>Casuarina equisetifolia</i>) which is considered an invasive tree, is another coastal mesic forest community. This community has the capability to grow in monospecific stands due to its aggressiveness in its nitrogen-fixing capability, ability to utilize brackish groundwater, and ability to exclude understory growth with its allelopathic leaves. Coconut (<i>Cocos nucifera</i>) trees introduced to Hawai'i by early Polynesian settlers are found along coastal beaches, sometimes in dense monotypic stands. Other areas that were once consisting of hala dominated species were farmed and subsequently abandoned by the ancient Hawaiians. These habitats have become dominated by common guava (<i>Psidium guajava</i>), strawberry guava (<i>P. cattleianum</i>), or black bamboo (<i>Phyllostachys nigra</i>), or by Polynesian introductions such as kamani (<i>Calophyllum inophyllum</i>), kukui (<i>Aleurites moluccana</i>), hau (<i>Hibiscus tiliaceus</i>), and tree heliotrope (<i>Tournefortia argentea</i>).

Fig. 4 Loulu coastal forest on the island of Nihoa.

native species may become naturalized or outcompete native species. For example, strawberry guava (*Psidium cattleianum*), a Brazilian native tree species, grows from sea level to 4000 ft in elevation (USFS, 2016). Strawberry guava competes with native species, fragments native habitat systems, alters water cycling of Hawaiian watersheds, and promotes secondary invasive species.

Ironwood (*Casuarina equisetifolia*) is an invasive species that is capable of fixing nitrogen and therefore, may alter the soil chemistry (Smith, 1992). It grows rapidly, forms exclusive stands, and its fallen branchlets produce allelopathic chemicals (Smith, 1992). In the NWHI, naupaka, a sand stabilizer of these islands, cannot tolerate the heavy shade from ironwood, thus has suffered from the gradual encroachment and eventual replacement by the invasive species (Smith, 1992). These low lying coastal islands are therefore more susceptible to erosive processes (Smith, 1992).

Koa haole (*Leucaena leucocephala*) is an aggressive pest due to its effective dispersal and potential for rapid population increase (Wester, 1992). Its ability to vigorously resprout and establish by seed after fire exhibits its ability to exploit new sites and shift the ecological systems (Smith and Tunison, 1992).

Coastal dry communities

Coastal dry communities have been inundated or replaced by invasive species such as pickleweed (*Batis maritima*), kiawe (*Prosopis pallida*), koa haole (*Leucaena leucocephala*), Christmas berry (*Schinus terebinthifolius*), sourbush (*Pluchea carolinensis*), guinea grass (*Megathyrsus maximus*). Native species are no longer dominant in the coastal dry forest (Gagné and Cuddihy, 1999); rather, the systems are made up of invasive plants as listed above and in Table 2.

Coastal wet-mesic communities

Coastal wet-mesic communities are represented by forests, generally restricted to the windward side due to the availability of rainfall, and in the NWHI and offshore islets (e.g., loulu valleys on Nihoa, ironwood stands on Midway, loulu on sea cliffs offshore of Moloka'i). Relative to other communities in the coastal system the coastal wet-mesic communities are relatively species-poor, but this may be a result of human alteration (Gagné and Cuddihy, 1999). Coastal mesic and wet forests have been significantly reduced to invasive dominated communities (see Table 3) (Figs. 5–8).

Current Biotic Components of Coastal Ecosystems

The honu, honu 'ea, and 'Ōlīoholoholoikauaua continue to use coastal areas, however, we speculate in less numbers than historic times. 'Ōpe'ape'a continue to forage in and off these habitats. Seabirds (Families: Sulidae, Fregatidae, Diomedidae, Procellariidae, Hydrobatidae, Laridae, Phaethontidae) are abundant on the NWHI. Honeycreepers and millerbirds continue to breed in coastal shrub communities in the NWHI. Flightless herbivorous birds, such as the moa nalo, are extinct. Native bees (*Hylaeus* spp.) may be found in remnant coastal communities in the main Hawaiian Islands and NWHI. Current threats to native species include introduced plants, mammals (rodents and ungulates), insects that negatively impact the native biota within the main Hawaiian Islands and NWHI in these coastal ecosystems (see below for discussion).

Fig. 5 Coastal ecosystem quality on the islands of Kaua'i and Nii'hau. From Reeves MK and Amidon F (2018) Habitat status assessment methods—Hawai'i, current condition summaries, August 2018. *Technical Report from United States Fish and Wildlife Service*, 439 pp. Honolulu, HI: Pacific Islands Fish and Wildlife Office.

Stressors

Development

Human development modified coastal ecosystems (Warshauer et al., 2009). Structures and sand hardening altered the hydrodynamics and water flow, wave regime, sediment dynamics, grain size, and depositional processes (Fletcher et al., 1997; Miles et al., 2001; Runyan and Griggs, 2003; Martin et al., 2005; Dugan et al., 2011). Beach hardening projects, including placement of seawalls, jetties, sandbags, and hardened structures, reduce coastal ecosystems, leading to the loss of coastal strand. These activities often result in sand compaction, erosion, and additional sedimentation in near-shore ecosystems, resulting in negative indirect effects to the ecological community and the ecosystem. Often, these increase erosion in adjacent areas and the potential for a cascading series of other beach stabilization projects (Fletcher, 2010; Coastal Geology Group, 2016).

When not managed, public access and recreation degrades or eliminates native communities. Vehicular access from tours, individual recreational access, and use of All Terrain Vehicles (ATV's) increases erosion and damages communities by crushing and breaking of native communities.

Ecosystem destruction and modification by urbanization and land use conversion lead to the direct fragmentation of coastal ecosystems and reduce native dominated coastal communities (Warshauer et al., 2009). Fragmentation decreases the total area of the ecosystem and native communities, reduces the diversity and composition of communities found in the ecosystem, and therefore reduces its resiliency (Figs. 9 and 10).

Biosecurity

Four agencies are responsible for inspection of goods arriving in Hawai'i. The Hawai'i Department of Agriculture (HDOA) inspects domestic cargo and vessels and focuses on pests of concern to Hawai'i, especially insects or plant diseases not yet known to be present in the State. The US Department of Homeland Security-Customs and Border Protection (CBP) is responsible for inspecting commercial, private, and military vessels and aircraft and related cargo and passengers arriving from foreign locations. They focus on a wide range of quarantine issues involving non-propagative plant materials (processed and unprocessed); wooden packing materials, timber, and products; internationally regulated commercial species under the Convention in International Trade in Endangered Species (CITES); federally listed noxious seeds and plants; soil; and pests of concern to the greater United States, such as

Fig. 6 Coastal ecosystem quality on the island of O'ahu. From Reeves MK and Amidon F (2018) *Habitat status assessment methods—Hawai'i, current condition summaries, August 2018. Technical Report from United States Fish and Wildlife Service*, 439 pp. Honolulu, HI: Pacific Islands Fish and Wildlife Office.

Fig. 7 Coastal ecosystem quality on the islands of Moloka'i, Lāna'i, Maui, and Kaho'olawe. Technical Report from United States Fish and Wildlife Service*, 439 pp. Honolulu, HI: Pacific Islands Fish and Wildlife Office.

Fig. 8 Coastal ecosystem quality on the island of Hawai'i. From Reeves MK and Amidon F (2018) *Habitat status assessment methods—Hawai'i, current condition summaries*, August 2018. *Technical Report from United States Fish and Wildlife Service*, 439 pp. Honolulu, HI: Pacific Islands Fish and Wildlife Office.

pests of mainland US forests and agriculture. The US Department of Agriculture-Animal and Plant Health Inspection Service-Plant Protection and Quarantine (PPQ) inspects propagative plant material, provides identification services for arriving plants and pests, conducts pest risk assessments, trains CBP personnel, conducts permitting and preclearance inspections for products originating in foreign countries, and maintains a pest database that, again, has a focus on pests of wide concern across the United States. The USFWS inspects arriving wildlife products, enforces the injurious wildlife provisions of the Lacey Act (18 U.S.C. 42; 16 U.S.C. 3371 *et seq.*), and prosecutes CITES violations.

The State of Hawai'i's unique biosecurity needs are not recognized by Federal import regulations. Under the PPQ's commodity risk assessments for plant pests, regulations are based on species considered threats to the mainland United States and do not address many species that could be pests in Hawai'i. Interstate commerce provides the pathway for invasive species and commodities infested with non-federal quarantine pests to enter Hawai'i. Pests of quarantine concern for Hawai'i may be intercepted at ports in Hawai'i by Federal agents but are not always acted on by them because these pests are not regulated under Federal mandates. Hence, Federal protection against pest species of concern to Hawai'i has historically been inadequate. It is possible for the USDA to grant Hawai'i protective exemptions under the "Special Local Needs Rule," when clear and comprehensive arguments for both agricultural and conservation issues are provided; however, this exemption procedure operates on a case-by-case basis

Fig. 9 Public parking lot and road at Ka'ena Point Natural Area Reserve entrance.

Fig. 10 ATV and off road trails with nonnative species.

and is extremely time-consuming to satisfy. Therefore, that avenue may only provide minimal protection against the large diversity of foreign pests that threaten Hawai'i.

Adequate staffing, facilities, and equipment for Federal and State pest inspectors and identifiers in Hawai'i devoted to invasive species interdiction are critical biosecurity gaps. State laws have recently been passed that allow the HDOA to collect fees for quarantine inspection of freight entering Hawai'i (e.g., Act 36 (2011) H.R.S. 150A–5.3). Legislation enacted in 2011 (H.B. 1568) requires commercial harbors and airports in Hawai'i to provide biosecurity and to facilitate cargo inspections. As described above, the introduction of new pests to the State of Hawai'i is a significant risk to coastal ecosystems.

Invasive animals

Introduced animals have impacted coastal native vegetation and native fauna. Impacts to native species and ecosystems accelerated following the arrival of Captain James Cook in 1778. This expedition and subsequent explorers intentionally introduced European pigs, goats and other livestock for food sources for seagoing explorers (Tomich, 1986; Loope, 1998). The mild climate of the islands and lack of predators led to the successful establishment of large populations of ungulates.

In these systems, ungulates disturb the soil, destroying vegetative cover and native vegetation. They create open areas conducive to further invasion by invasive plants.

Dogs, cats, and mongoose also affect coastal ecosystems: dogs trample plants; mongoose opportunistically eat insect pollinators, fruits, and native plants; and cats spread the parasite, *Toxoplasma gondii*, in feces that affect 'iliholoakauaua.

Three species of introduced rats, Polynesian rat (*Rattus exulans*), black rat (*Rattus rattus*), and Norway rat (*Rattus norvegicus*), impact the coastal communities within the ecosystem. Omnivorous rats eat fleshy fruits, seeds, flowers, stems, leaves, and roots (Atkinson and Atkinson, 2000), strip bark and cut small branches (twig cutting) in search of moisture and nutrients, and seriously affect the vigor and regeneration of vegetation (Abe and Umeno, 2011; Nelson, 2012). In the Hawaiian Islands, rats may consume as much as 90% of seeds produced by some native plants, and in some cases prevent regeneration of species completely (Cuddihy and Stone, 1990). Hawaiian plants are particularly susceptible to rat predation because the successful reproduction is affected (Cuddihy and Stone, 1990). Given their impacts on native vegetation, rats have the potential to significantly alter coastal communities.

The introduced house mouse (*Mus musculus*) is most common in lowland ecosystems and abundant over a wide range of vegetation types (Cuddihy and Stone, 1990). Mice have been documented eating insects, grass seeds, fruits (Kami, 1966), and may disrupt plant pollination through destruction of larvae of pollinators (Cole et al., 2000; Cuddihy and Stone, 1990).

Invasive insects

Sometimes when invasive invertebrates feed on or defoliate native plants, the ranges of the native plants are reduced. For example, the erythrina gall wasp (*Quadrastichus erythrinae*) is an invasive invertebrate that impacts wiliwili trees (*Erythrina sandwicensis*). The gall wasp was first discovered on O'ahu in 2005 and subsequently spread to other main Hawaiian Islands (Heu et al., 2008). Like other gall-forming wasps, they insert eggs into young leaf and stem tissue. Larvae develop and eventually cut exit holes to emerge as adults. Heavily galled plants result in a loss of growth and vigor, while severe infestations lead to defoliation and death (Heu et al., 2008; Yang et al., 2004). As a destructive pest on native wiliwili trees, this wasp impacts coastal communities (by what? Please make this clear).

The black twig borer (*Xylosandrus compactus*), first discovered on O'ahu in 1961, has become widespread throughout the main Hawaiian Islands (Nelson and Davis, 1972). Black twig borers tunnel into woody twigs or branches to lay their eggs. This excavation and the introduction of pathogens damages the host. Severe infestation can kill host plants, including large trees (Tenbrink and Hara, 2007; Nelson and Davis, 1972). Black twig borers have also infested invasive understory shrub species (koa haole and Christmas berry (*Schinus terebinthifolia*)) (Nelson and Davis, 1972).

Naio thrips (*Klambothrips myopori*) was first detected on Hawai'i Island in 2008, attacking the native naio (HDLNR et al., 2013). Thrips feed on the host plant's foliage, resulting in leaf distortion and galls. Heavy infestations lead to leaf curling, dieback, defoliation, and mortality (HDLNR et al., 2013). These trips also impacts native insect herbivores and pollinators that rely on naio for food and/or habitat (HDLNR et al., 2013).

Invasive ants (Family Formicidae) including the big-headed ant (*Pheidole megacephala*), yellow crazy ant (*Anoplolepis gracilipes*), *Solenopsis papuana*, *S. geminata*, longhorn crazy ant (*Paratrechina longicornis*), *Tetramorium bicarinatum*, *T. simillimum*, bicolored trailing ant (*Monomorium floricola*), ghost ant (*Tapinoma melanocephalum*), *Cardiocondyla kagutsuchi*, *C. venustula*, and little red fire ants (*Solenopsis geminate*) compete with and displace native invertebrates for nectar food and nesting resources (Howarth, 1985; Hopper et al., 1996; Holway et al., 2002; Daly and Magnacca, 2003; Lach, 2008).

Gray bird grasshopper (*Schistocerca nitens*) has the potential to completely defoliate the native vegetation and has been documented on the island of Nihoa (Latchininsky, 2006, 2008; Plentovich et al., 2015). *S. nitens* feeds on broad-leaved plants and avoid grasses (Latchininsky, 2006; Plentovich et al., 2015). *S. nitens* outbreaks in 2002 and 2004 on the island of Nihoa posed a major threat to the vegetation (Gilmartin, 2005), especially to endangered plants (Plentovich et al., 2015).

Invasive plants

The historic flora consisted of approximately 1000 taxa, 89% of which were endemic. Over 800 plant taxa have been introduced, and nearly 100 of these are considered pests (Smith, 1985; Cuddihy and Stone, 1990; Gagné and Cuddihy, 1999). Some plants were brought for food or cultural reasons and are well established along coastlines (Cuddihy and Stone, 1990). Plantation owners and the territorial government of Hawai'i introduced nonnative trees for reforestation to protect water resources. Ranchers intentionally introduced pasture grasses and other nonnative plants for agriculture, and sometimes inadvertently introduced weeds. Other plants were brought for horticultural value (Scott et al., 1986; Cuddihy and Stone, 1990). Invasive plants compete for resources; modifying the availability of light; altering soil-water regimes; modifying nutrient cycling processes; altering fire characteristics of native ecosystems; lead to incursions of fire-tolerant nonnative plant species; and indirectly inhibit the growth requirement of native species (e.g., ironwood). Nonnative tree species constitute the greatest threat within coastal strand communities, especially if they can disperse readily and form dense thickets above native vegetation (Warshauer et al., 2009).

Fire

Although the number and size of wildfires have increased on the main Hawaiian Islands; their occurrences are unpredictable (Gima, 1998; County of Maui, 2009; Hamilton, 2009; Honolulu Advertiser, 2010; Pacific Disaster Center, 2011). Fires may create open ecosystems for invasive plants to exploit (D'Antonio and Vitousek, 1992). For example, Fountain grass (*Pennisetum setaceum*) is a fire-adapted nonnative plant that produces a high fuel load that increases fire intensity; the species regenerates quickly after

fire and establishes rapidly in burned areas (Fujioka and Fujii 1980 in Cuddihy and Stone, 1990; D'Antonio and Vitousek, 1992; Tunison et al., 2002).

Storms

Hurricanes exacerbate the impacts of other threats. By destroying native vegetation, hurricanes open tree canopy, modify the availability of light, and create disturbed areas conducive to invasion by invasive plants (Asner and Goldstein, 1997; Harrington et al., 1997). Major tsunamis occur worldwide about once every 10 years, on average, and almost 60% of those occur in the Pacific Ocean (Pacific Tsunami Warning Center, 2009). In 2011, a tsunami caused by an earthquake in Japan swept over Kuaihelani's Eastern Island and Hōlanikū's Green Island, where it inundated plants, spread plastic debris, as it traveled inland and had devastating effects to the native biota (Leary, 2011).

Flooding and erosion

In the open sea near Hawai'i, rainfall averages 630–760 mm per year, and some places may receive up to 15 times this amount, depending on topography (Wagner et al., 1999). Rain may fall at rates of 76 mm per hour and reach 1000 mm in 24 h, and the flash floods bring sediments down streams and narrow gulches; which may damage, destroy, or eliminate one or more isolated occurrences of native plants that persist in low numbers and limited geographic range due to invasive plants (Wagner et al., 1999). This compromises the redundancy and resilience of the ecosystem.

Sea level rise

According to the Intergovernmental Panel on Climate Change, the oceans are now absorbing more than 90% of the heat added to the Earth's climate ecosystem (Bindoff et al., 2013 and Rhein et al., 2013 as cited in Bindoff et al., 2019). Since 1961, this absorption has caused average global ocean temperatures to increase, seawater to expand, and sea-levels to rise. Melting ice-sheets, ice caps, and alpine glaciers also influence ocean levels. Analysis of the historical record indicates ocean surface temperature in Hawai'i has been increasing over the past century, and accelerated since the 1970s (Fletcher, 2010). Although coastal ecosystems will likely move inland as sea-level rises, low elevation islands are predicted to completely become affected by increased erosion and exposed to marine inundation (Fletcher, 2010).

Interactive conservation actions

Impacts from stressors are addressed through active management (e.g., predator and invasive species control, fencing, outplanting, etc.), land protections, laws and regulations, and education and outreach. These approaches are implemented by state and federal government agencies, private organizations, and non-government organizations (NGOs) (Table 4). Given that land ownership of this ecosystem is spread among these parties, partnerships are also formed to manage the ecosystem collectively. Many of the organizations and agencies that contribute to the protection and management of coastal areas are described in Table 4. The laws and regulations governing the work in Hawai'i may be found in Table 5.

Summary of Interactions

The two most significant stressors of coastal ecosystems are the conversion/fragmentation of land due to development pressure, and the ongoing impact of invasive species. The laws, regulations, land protection, and management actions are not currently enough to prevent the overall decline of native coastal ecosystems. The rate of native coastal ecosystem decline is associated with development pressure (e.g., O'ahu, Maui, Kaua'i, and Hawai'i). In these areas the fragmentation reduces resiliency, and the systems are unable to withstand normal stochastic events. Throughout coastal ecosystems, invasive animals and plants outcompete native species, resulting in invasive-dominated coastal communities.

Future Scenarios

Three conservation management parameters (CMPs) will drive the condition of coastal ecosystems into the future. These conservation parameters capture the social and legal mechanisms under which natural resource conservation is carried out. The CMPs are as follows:

- (1) *Conservation Values*: stakeholder involvement and public opinion determine the formulation, implementation and funding of natural resource conservation.
- (2) *Laws and Biosecurity*: national, state, county, and city regulations are the means by which natural resource conservation and biosecurity are implemented. (e.g., hunting regulations, Clean Water Act, Endangered Species Act, local laws, etc.).
- (3) *Development or Conservation Planning*: planning for development, protection, or both will result in losses or gains in natural resource conservation or biosecurity and implementation of these plans are key.

Table 4 Conservation efforts of multiple organizations and agencies.

<i>Protected area</i>	<i>Location information</i>	<i>Landowner/manager</i>	<i>Protected acreage (ac)</i>	<i>Conservation importance</i>
Hono O Nā Pali NAR:	Kaua'i	Hawai'i Department of Land and Natural Resources (DLNR)	These cliffs are dominated by common coastal plants such as kāwelu (<i>Eragrostis variabilis</i>), 'āhinahina (<i>Artemisia australis</i>), 'akoko, nehe, ko'oko'olau, 'ilima (<i>Sida fallax</i>), and akoko (<i>Chamaesyce celastroides</i>)	Lowland coastal systems containing steep cliffs characterized by plants found in drier areas
Ka'ena Point NAR	O'ahu	DLNR	A nesting area for the Laysan albatross and rest area for 'ilioholoholoikaua	Protection of coastal dry shrublands and rare coastal plants.
Oloku'i NAR	Moloka'i	DLNR	The reserve encompasses the mountain plateau to sea cliffs and is one of the very few areas undisturbed by feral ungulates	Protection of coastal dry grasslands
'Ahihi-Kina'u NAR	Maui	DLNR	The area contains examples of pioneer vegetation that serve as systems for rare plants, insects, and birds	Protection of coastal dry shrublands, coastal mesic communities
Manuka NAR	Hawai'i Island	DLNR	Unit extends from 600 ft. (183 m) in elevation down to the coastal boundary Low goat damage found in the coastal regions (State of Hawai'i 2018).	Protection of coastal dry shrubland ('ilima dominated) and lowland dry grasslands (pili)
Pu'u O Umi NAR	Hawai'i Island	DLNR		This reserve contains dry coastal sea cliffs, coastal dry shrublands and grasslands.
Haleakalā National Park, Kīpahulu District	Maui	National Park Service (NPS)	Located on the east side of Maui, the Kīpahulu District protects an intact ahupua'a (traditional native Hawaiian land division)	Protection of native coastal strand of hala and naupaka communities
Kalaupapa National Historical Park	Moloka'i	NPS	The park's boundary extends for a quarter mile offshore and includes 2000 acres of ocean, two small offshore islands, and wet shorelines. The offshore islands of 'Ōkala and Huelo support coastal mesic system for loulou and the endemic pua'ala (<i>Brighamia rockii</i>). On the ground management such as invasive plant control, fencing, and ungulate removal are conducted.	
The Ala Kahakai National Historic Trail, Kaloko-Honokōhau National Historical Park, Pu'ukoholā Heiau National Historic Site, Pu'uhonua o Hōnaunau National Historical Park,	Hawai'i	National Park Service (NPS)		Although the main purpose of these parks are cultural and public use, the coastal system management conservation actions exist to maintain the processes and native strand system that allow these areas to persist.
'Āpua Point, Keauhou, Halapē, and Ka'aha	Hawai'i	NPS	Coastal areas within the NPS's Hawai'i Volcanoes National Park that span approximately 20 miles across the coastline.	Contains dry coastal herblands, grasslands, and shrublands. Actions to conserve the coastal system in the park include endangered species monitoring and recovery, system restoration, nonnative plant and animal management, and fire ecology.

Table 4 Conservation efforts of multiple organizations and agencies.—cont'd

<i>Protected area</i>	<i>Location information</i>	<i>Landowner/manager</i>	<i>Protected acreage (ac)</i>	<i>Conservation importance</i>
Kiholo bay	Hawai'i	The Nature Conservancy (TNC) of Hawai'i	7 ac (3 ha)	Contains a vital interface between land and coastal waters, providing system for native flora and fauna.
Mo'omomi Preserve	Moloka'i	TNC managed in partnership with DLNR through the Natural Area Partnership Program.	Preserve is 921 acres (373 ha)	Sand dunes and beach system. Portions of the preserve dunes are lithified (sand dunes that become solidified) and are distinct in geological appearance and native strand.
Kamehame beach	Hawai'i	TNC	20 ac (8 ha)	Protection of nesting habitat for honu 'ea. System consists of naupaka with other coastal plants like 'aki'a, naio, and pā'u o Hi'iaka.
Akoakoa	Hawai'i	Kamehameha Schools	Three acre (1 ha)	Coastal bluff located along the Kohala; managed for ungulates and invasive plants; restoration of common native plants.
Koholālele	Hawai'i	Kamehameha Schools		Coastal bluff along Hāmākua coast; restoration of native, food, and canoe plants.
Kahanu Preserve	Maui	National Tropical Botanical Garden (NTBG)	122 ac (49 ha) unit	Contains the last remaining coastal wet forests in Hawai'i (dominated by hala trees); preserve is located in a key part of the larger coastal wet forest adjacent to Kahanu Garden and Pi'ilanihale Heiau.
Lāwai Kai	Kaua'i	NTBG	80 ac (32 ha)	The garden is situated next to Lāwa'i bay, important habitat for honu.
Coastal systems protected by conservation easements at Keopuka, South Kona, and Kaiholena, Kohala.	Hawai'i	Hawaiian Islands Land Trust (HILT)	More than 277.5 ac (112 ha)	These lands are conserved for shoreline and open space.
Conservation easement at Maka'ala, Hana; Hawea, Kapalua; and Papa'ula, Wailuku; Kipahulu; Kaulahao; and Hana Kakio II as well as fee ownership at the Waihe'e	Maui	HILT	More than 467.63 ac (189 ha)	For the protection of coastal dunes
Purchase of Honolulu/Lipoa	Maui	HILT	Over 244 ac (99 ha)	To preserve coastal system.
Coastal system protected by conservation easement at Pohaku Pili	Moloka'i	HILT	over 76 ac (31 ha)	To preserve coastal system.
Wainiha and Kahili Beach Preserves are owned by HILT	Kaua'i	HILT	Over 18 ac (7 ha)	Protection of coastal system
Conservation easement at Waikalua	Kaua'i	HILT	Over 18 ac (7 ha)	Protection of coastal system
Coastal system protected by the assistance of HILT at Kahili Beach and Hanalei/Black Pot Beach Park Expansion.	Kaua'i	HILT	Approximately 3.7 ac (1.5 ha)	Protection of coastal system
Assisted with the purchase and conservation of Awāwamalu (Ka 'Iwi Coast) and the North Shore.	O'ahu	HILT	Over 812 ac (329 ha)	Protection of coastal system

Table 5 Hawai'i laws and regulations related to conservation.

<i>Title</i>	<i>Year implemented</i>	<i>Authority</i>	<i>Intent/purpose</i>
Endangered Species Act	1973	Federal (USFWS and NMFS)	Protects critically imperiled species from extinction
50 CFR 16	1974	Federal	Implements the Lacey Act (18 USC 42), which prohibits importation of injurious species
Convention on International Trade in Endangered Species	1975	International	Ensures that international trade in specimens of wild animals and plants does not threaten the survival of the species in the wild
Executive Order 11987	1977	Federal	Charges Executive agencies with restricting the introduction of exotic species into the natural ecosystems on federal lands; and encourages States to do the same
Hawai'i Administrative Rules, Title 4, Subtitle 6, Chapters 68 and 70	1981	Hawai'i (Department of Agriculture)	Rules/amendments for noxious weeds, plant and non-domestic animal quarantine, plant import, and bromeliad import
Executive Order 13112	1999	Federal	Requires that a Council of Departments dealing with invasive species be created to prevent the introduction of invasive species and provide for their control and to minimize the economic, ecological, and human health impacts that invasive species cause
HRS 194-2	2002	Hawai'i (Department of Land and Natural Resources)	Establishes Hawai'i Invasive Species Council (HISC)
Act 85	2003	Hawai'i (HISC)	Conveys statutory authority to HISC to continue to coordinate approaches among the various State and Federal initiatives for the prevention and control of invasive species
HRS Chapter 205A for Coastal Zone Management	2006	Hawai'i (DLNR)	To preserve, protect, and where possible, to restore the natural resources of the coastal zone of Hawai'i
Act 36 (2011) HRS 150A-5.3	2011	Hawai'i (DOA)	Imposes a fee for the inspection, quarantine, and eradication of invasive species contained in any freight brought into the State
HB 1568	2011	Hawai'i (DOA)	Requires commercial harbors and airports in Hawai'i to provide biosecurity and to facilitate cargo inspections
HRS 174C Hawai'i State Water Code	2013	Hawai'i (CWRM)	Establishes Commission on Water Resource Management and Water Resource Management Fund
Executive Order 13751	2016	Federal	To prevent the introduction of invasive species and provide for their control, and to minimize the economic, plant, animal, ecological, and human health impacts that invasive species cause (amends EO 13112)
7 CFR 360.200	2018	Federal	Designates certain plants as noxious weeds

The year 2035 is the extent of the “foreseeable future,” and is based on the projected divergence of IPCC Representative Concentration Pathway (RCP) climate change scenarios (van Vuuren et al., 2011a,b). The foreseeable future scenarios considered in this ecosystem assessment are explained below.

Future Scenario One

Scenario One is the status quo, and considered to be the most likely future scenario, and serves as a “baseline” for comparing the future scenarios. There is no change in the implementation of the three CMPs between 2018 and 2035. The current rate of change in land cover will continue through the foreseeable future. Human populations and residential, commercial, and agricultural land development will likely continue to expand, causing ecosystem stressors to continue to increase. It is also probable that Coastal Dry: Herblands, Grasslands, Shrublands, Mixed Communities; and Coastal Wet-Mesic Forests will continue to decline in extent, quality, and function. Native vegetation will continue to give way to an invasive dominated landscape. Resorts and residential communities along coastlines will expand. As development pressure continues, the remaining coastlines will become more fragmented and will be less resilient to stochastic events.

The conditions of each coastal sub-type will continue to slowly decline in Scenario One. Coastal areas will continue to decline in extent and function due to impacts from feral ungulates. High priority invasive weed species, such as koa haole and Christmas berry will expand along coastlines and form monotypic stands. Under a continuation of current bio-security laws, it is likely that new pathogens, diseases, and invasive plant and animal species will be introduced to coastal ecosystems. Erosion will increase, particularly along coastal bluffs, cliffs, and areas prone to strong wave energy. Drought and fire will marginalize the coastal strand. Sea level will rise approximately 1.5 mm per year or more (Coastal Geology Group, 2008) and low lying islands in the NWHI (Laysan, Lisianski, Pearl and Hermes, Midway, French Frigate Shoals, and Kure) will be vulnerable to wave-driven flooding or submersion.

Future Scenario Two

A slight increase in the CMPs marginally improves conservation management. Conservation Agencies and stakeholders work with increased but limited resources to slow or stop the degradation of landscape areas. Although the human population increases, development does not substantially increase. A slightly improved biosecurity effort reduces invasive species but some plant diseases but increases are still expected. The small increased support of natural resource management does not alter wildfire frequency or intensity much beyond Scenario One.

The CMP-supported conservation does not prevent, mitigate, or reverse the impacts of climate change-related stressors. Coastal Dry Herblands, Grasslands, and Shrublands, Mixed Communities, and Coastal Wet-Mesic Forests will continue to show a decline in extent, quality, and function. An increase in invasive plants and feral ungulates dominate the landscape. As development continues with the construction of resorts and residential communities, coastal ecosystems decrease in area. However, slight growth in natural resource conservation and biosecurity results in conservation easements. Agencies slightly increase management efforts by strategically fencing areas which protect bio-diversity in native coastal systems. Sea level rise impacts coastal zones as in Scenario One.

Future Scenario Three

There is a small to moderate decrease in conservation actions in the CMPs that relaxes biosecurity controls, resulting in reduced conservation efforts. An expanding human population requires increased land use for agriculture and development. Economic development outpaces conservation. Nonnative plants and recreation areas will expand. Feral ungulate populations will grow. Wildfire will increase. Coastal Dry Herblands, Grasslands, and Shrublands, Mixed Communities; and Coastal Wet-Mesic Forests will be severely reduced in extent, quality, and function. With extensive localized management, some native plant species may persist in park-like settings or in areas where land development is not possible. The value of current conservation easements and protected areas will diminish and sales of protected lands by private companies and NGO's could expand and facilitate development. As fragmentation increases in these coastal ecosystems, an invasive-dominated ecosystem will occur.

Future Scenario Four

There is a moderate to large increase in conservation actions in the CMPs that substantially improves conservation through a robust effort to engage stakeholders to identify and prioritize landscapes needed for conservation and restoration. The needs of an expanding human population are addressed through more efficient land use governance based on redevelopment rather than development of undeveloped areas. Modern and novel agricultural practices focus on those that do not affect existing natural areas or areas needed for native ecosystem restoration. Substantially improved biosecurity regulations decrease introductions of invasive species and plant diseases. These improved land management actions result in the decreased extent and frequency of wildfire. Climate change-related stressors continue but resiliency increases.

Abstract

The Mariana archipelago consists of an island arc formed as the Pacific plate converges with the Philippine plate in a subduction zone where the older, more dense Pacific plate sinks and moves underneath the Philippine plate creating the deepest location known on earth—the Marianas Trench. The islands in the north part of the arc are younger, active volcanoes, whereas the older islands in the south are volcanic remnants that have layers of limestone from a time when they were once below sea level. The Mariana archipelago has two distinct seasons, wet, and dry. The climate is mild; however, the archipelago is prone to typhoons. Because the Mariana archipelago has no elevation extremes, it does not host a wide variety of biomes. Here we focus on the physical features of the Mariana archipelago.

Geography

The Mariana archipelago consists of 15 main islands and various small islets spanning a north-south distance of 553 miles (mi) (890 kilometers (km)) in the western Pacific Ocean between latitudes 21° and 13°N and longitudes 144° and 146°E. The vast majority of the archipelago's land area is concentrated in the larger, southern main islands, including Saipan, Tinian, Rota, and Guam.

Geology

The islands within the Mariana archipelago vary in age between 5 million years in the north and 50 million years in the south. The archipelago was formed by the ongoing collision of the Pacific and Philippine tectonic plates at the Mariana Trench, which resulted in both uplifting and volcanic activity creating a chain of mountains protruding from the sea floor (Fig. 2) (Raulerson and Rinehart 1992, p. 3; Vigil and Tilling, 2006, entire). Primarily volcanic in origin, the northern portion of the archipelago (north of Farallon de Medinilla) includes both relatively active volcanic islands (Anatahan, Pagan, and Uracas) as well dormant volcanic islands (Agrihan, Alamagan, Asuncion, Guguan, Maug, and Sarigan). The geologically more complex, limestone and volcanic southern islands, including Aguiguan, Guam (with the adjacent Cocos Island), Rota, Saipan, and Tinian, have been historically and regularly

inhabited by humans. All of the other islands in the archipelago are currently uninhabited, although some, including Agrihan, Agui-guan, Alamagan, Anatahan, Pagan, and Sarigan have been historically inhabited by the Chamorro, and are still visited on occasion (Fig. 1).

Substratum

The complex substratum of the older southern islands is comprised of plateaus of ancient limestone seabed pushed up with the tectonic plate, rolling volcanic hills and mountains, and more relatively recent coral limestone formations (Ohba 1994, p. 14; Mueller-Dombois and Fosberg, 1998, p. 241; Carruth, 2003, p. 3; Gingerich, 2003, p. 1; Taborosi, 2004, pp. 8–13; Berger et al., 2005, p. 9). The younger northern islands, largely composed of black volcanic basalts, are typical cone-shaped stratovolcanoes (steep, many-layered volcanoes characterized by periodic, explosive eruptions) with steep slopes and often eroded with deep ravines (Ohba, 1994, p. 14; Mueller-Dombois and Fosberg, 1998, p. 241). As noted above, many of the northern islands (Anatahan, Pagan, and Uracas) remain volcanically active. Areas of exposed weathered volcanic substratum can be found on the southern islands, particularly in the middle of Saipan and on the southern half of Guam (Mueller-Dombois and Fosberg, 1998, p. 241). Extensive cave formations also occur within the karst topography of the southern islands of Saipan, Agui-guan, Rota, and Guam (Taborosi et al., 2003, pp. 1). Some northern islands also exhibit limited cave systems including lava tubes and related crevices.

Hydrology

The ultimate source of all freshwater in the Mariana archipelago is rainwater (Carruth, 2003, p. 2; Gingerich, 2003, p. 1; Falkland et al., 1991, p. 6). Some rainwater escapes to the atmosphere by evaporation and transpiration, some flows directly to the sea in streams, and some moves downward through the soil and rock to ground-water reservoirs and then into springs and seeps that discharge into streams or directly into the sea (Ward et al., 1965, p. H6). The occurrence of groundwater resources in small islands is a function of geomorphology, size, geology, and other factors. The larger the island, the more likely it will have a fresh

José F. Vigil and Robert I. Tilling

Fig. 2 Formation of the Mariana archipelago. From Vigil, J.F. and R. Tilling. (2006). Schematic cross section of plate tectonics. In: Simkin, T., Tilling, R.I., Vogt, P.R., Kirby, S.H., Kimberly, P. and Stewart, D.B. (eds.). *This dynamic planet: World maps of volcanoes, earthquakes, impact craters, and plate tectonics. Geological investigations Map I-2800: the dynamic planet*. Image: U.S. Geological Survey.

groundwater body (Falkland et al., 1991, p. 41). Similarly, a more circular island will have more opportunity for developing groundwater than an elongated island of similar size (Falkland et al., 1991, p. 41). The flow in streams and the recharge and discharge of groundwater differ greatly with locality depending on the character of the rock (Ward et al., 1965, p. H6).

The highest volume of rainwater is captured on the older, southern islands, due to their abundance of limestone substratum which has much greater permeability than the predominant volcanic substratum of the northern islands. However, limestone varies in permeability due to geologic age, formation, and general character and distribution (Ward et al., 1965, p. H5; Carruth, 2003, p. 4). Due to its permeability, limestone substratum does not support surface water, whereas the less permeable volcanic substratum supports surface water (Falkland et al., 1991, p. 6). The permeable limestone allows rain to percolate into the ground instead of flowing on the surface (Taborosi, 2004, p. 15). Driven by gravity, the water moves underground through air-filled fractures, voids, and conduits, and enlarges and connects them by dissolution (Taborosi, 2004, p. 15). It reaches the groundwater level and a fresh groundwater body known as the freshwater lens is formed (Taborosi, 2004, p. 15) (Fig. 3). Groundwater discharge in volcanic terrane areas is mostly at seeps and springs dispersed along the streams (Ward et al., 1965, p. H6). Watersheds or drainage basins occur in such areas. As the rainfall decreases at the end of the wet season, streamflow on volcanic terrane recedes rapidly to the low flow maintained by the slow discharge of groundwater from the volcanic rock (Ward et al., 1965, p. H7). The absence of rainfall for only three or four weeks can cause a serious shortage in streamflow in some volcanic rock areas (Ward et al., 1965, p. H7). For example, there are no surface rivers on the northern part of Guam which is composed primarily of limestone, and numerous rivers and streams in the south due to its volcanic substratum. However, as with other small islands, river discharge rates in southern Guam fluctuate depending on rainfall volume and distribution over the year (Falkland et al., 1991, p. 7).

The freshwater lens floats on saltwater and is separated from the saltwater by a transition zone of brackish water. This freshwater lens sits just below the lowest water table (Gingerich, 2003, p. 2). The freshwater, brackish water, and saltwater are all part of the freshwater-lens system. Salinity in a freshwater-lens system is gradational, from an upper freshwater core through the underlying transition zone to saltwater. Minor perched systems can exist above the lowest water table. Groundwater flows from areas of high water level to areas of low water level, which in general, is from the interior of the island to the coast. A summary of the geological and hydrological features of the Mariana archipelago are provided in Table 1.

Fig. 3 Example of hydrologic cycle on the southern islands in the Mariana archipelago: rain water percolates through the limestone into a freshwater lens on eastern Saipan. From Carruth, R.L. (2003). Ground-water resources of Saipan, Commonwealth of the Northern Mariana Islands. U.S. Geological Survey Water-Resources Investigations Report 03-4178, p. 3, U.S. Geological Survey.

Table 1 Geological and hydrological summary of the Mariana archipelago.

Island (south to north)	Features and attributes				
	Emergent area mi^2 (km^2)	Highest elev. ft. (m)	Highest point	Volcanic activity	Surface water features
1 Guam	210 (540)	1334 (407)	Mount Lamlam	No	Streams, rivers, wetlands
2 Rota	33 (85.4)	1611 (491)	Mount Manira	No	Streams, wetlands
3 Aguiguan	2.74 (7.1)	515 (157)	Alutom	No	Seeps
4 Tinian	39 (101)	613 (187)	Mount Kastiyu	No	Wetland
5 Saipan	44.5 (115.38)	1555 (474)	Mount Tapochau	No	Streams, wetlands
6 FDM	0.33 (0.85)	266 (81)	NA	No	Ephemeral seeps
7 Anatahan	12 (31.2)	2582 (787)	NA	2008	Ephemeral streams, seeps
8 Sarigan	1.92 (4.97)	1801 (549)	NA	Holocene	Ephemeral streams, seeps
9 Guguan	1.5 (3.87)	988 (301)	NA	1883	Ephemeral streams, seeps
10 Alamagan	4.29 (11.11)	2441 (744)	Alamagan	870 CE	Ephemeral streams, seeps
11 Pagan	18.24 (47.24)	1900 (579)	Mount Pagan	2012	Lakes, ephemeral streams, seeps
12 Agrihan	16.8 (43.51)	3166 (965)	Mount Agrihan	1917	Ephemeral streams, seeps
13 Asuncion	2.82 (7.31)	2923 (891)	NA	1906	Ephemeral streams, seeps
14 Maug	0.82 (2.13)	745 (227)	North Island	$\geq 1500\text{s}$	Ephemeral seeps
15 Uracas	0.98 (2.5)	1047 (319)	NA	1967	Ephemeral seeps

Climate

The relatively low elevation (the highest point in the archipelago occurring on the island of Agrihan at 3166 ft. (965 m), juxtaposed with the close proximity to the equator and shallow seas to the west, insulate the Mariana archipelago from seasonal variation in weather creating one of the most stable climates in the world. According to the Koeppen Climate Classification, the entire archipelago is classified as Af, which refers to an equatorial or equatorial and fully humid climate, also sometimes referred to as tropical rainforest climate or tropical wet climate. Another key climate driver in the region is the pronounced annual monsoon season in the region which results in a distinct wet and dry season lasting 3–4 months each.

Temperature, Rainfall, and Monsoon Season

Despite a small number of weather stations in the Mariana archipelago, resulting in limited available meteorological data, the climate in the Mariana archipelago is uniquely stable, in particular with temperature as highs and lows range between 86°F and 73°F (30–22.8°C). However, due to the monsoon season in the western Pacific, the Mariana archipelago exhibits a notably wetter season from July through October, and a drier season from November through June, with April characteristically being the driest month of the year (Ohba, 1994, p. 16; Mueller-Dombois and Fosberg, 1998, p. 241) (Figs. 4 and 5).

Precipitation within the archipelago averages 96 in (218 cm) per year, dependent in part on elevation. Although none of the islands receive rainfall as a result of an orographic effect (mountains forcing moist air to rise and lose their moisture as rain), some of the tallest peaks experience more frequent cloud cover and slightly cooler temperatures. This is particularly true for the northern island summits of Anatahan, Alamagan, Pagan, and Sarigan (Dahl, 1980, pp. 22, 64; Ohba, 1994, pp. 18, 41, 48). The Mariana archipelago receives relatively constant trade winds most of the year, however during the summer months, storms and typhoons originating from the southeast and east occur frequently and typically pass by the archipelago on their journey to shallower seas to the east. An average of at least one typhoon per year impacts the Mariana archipelago (Mueller-Dombois and Fosberg, 1998, p. 241; Japan Meteorological Agency, 2019), and category 5 typhoons are not uncommon (Fig. 6).

Mariana Archipelago: Island Descriptions

Guam

Guam is located in the northwestern Pacific Ocean, 1200 mi (1930 km) east of the Philippines, 3500 mi (5632 km) west of the Hawaiian islands, and 54 mi (87 km) south of Rota. It is the largest and southernmost island of the Mariana archipelago with a land-mass of 216 mi^2 (mi^2) (560 square kilometers (km^2))—comparable in area to the Hawaiian island of Molokai. It is nearly 31 mi (50 km) long and from 4 to 9 mi (7–15 km) wide with a peak elevation of 1332 ft. (406 m) at Mt. Lamlam (Mueller-Dombois and Fosberg, 1998, p. 269).

The northern and southern regions of the island show marked contrast due to their geologic origin. The northern region is an extensive, upraised, terraced, limestone plateau or “mesa” between 300 and 600 ft. (90 and 180 m) above sea level interrupted by a few low hills, of which two (Mataguac and Mt. Santa Rosa) are volcanic in nature, while others are exclusively coralline limestone (e.g., Barrigada Hill and Ritidian Point) (Stone, 1970, p. 12). The southern region is primarily composed of volcanic mountains

Fig. 4 Seasonal temperature in the Mariana archipelago. Data extracted from Harris, I., Jones, P. D., Osborn, T. J. and Lister, D. H. (2014). Updated high-resolution grids of monthly climatic observations—CRU TS3.10: The Climatic Research Unit (CRU) Time Series (TS) Version 3.10 Dataset. *International Journal of Climatology* **34** (3), 623–642, doi: 10.1002/joc3711; updated from previous version of CRU TS3.xx (most recent use in CCKP: TS3.24). U.S. Fish and Wildlife Service, Pacific Islands Fish and Wildlife Office.

with several areas capped by a layer of limestone (Stone, 1970, p. 12). Within the Mariana archipelago, Guam contains the most extensive stream and drainage systems, particularly in the southern Talofofo Region (Stone, 1970, p. 13; Mueller-Dombois and Fosberg, 1998, p. 269). Fairly extensive wetland areas are found on the southern coasts as well and at Agana Swamp located in the middle of the island.

Rota

Located approximately 36 mi (58 km) northeast of Guam and 47 mi (76 km) southwest of Aguiguan, Rota is the fourth largest island in the Mariana archipelago, measuring 33 mi² (96 km²) (Mueller-Dombois and Fosberg, 1998, p. 265; CNMI-SWARS, 2010, p. 6). Rota consists primarily of terraced limestone surrounding a volcanic core that protrudes from the topmost plateau, known as Mount Sabana or Mount Manira, which is also the highest point on the island at 1611 ft. (491 m) (Mueller-Dombois and Fosberg, 1998, p. 265).

Aguiguan

Located approximately 47 mi (76 km) north of Rota and 7 mi (9 km) south of Tinian, Aguiguan is a small uninhabited island measuring 7 mi² (18 km²) with a peak elevation of 515 ft. (157 m) at Mt. Alutom (CNMI-SWARS, 2010, p. 6). Aguiguan is also known as “Goat Island” due to the presence of a fluctuating, but often large, feral goat population (Engbring et al., 1986, p. 8; Liske-Clark, 2015, p. 4–10). Geologically, Aguiguan is entirely limestone with very steep cliffs fringing most the island making access difficult (Engbring et al., 1986, p. 36). Hydrology on the island consists of a few freshwater seeps (Engbring et al., 1986, p. 8).

Tinian

Located approximately 7 mi (9 km) north of Aguiguan and 3 mi (5 km) southeast of Saipan, Tinian is the third largest island in the Mariana archipelago, measuring 40 mi² (101 km²) with a peak elevation of 613 ft. (187 m) at Mount Kastiyu (Engbring et al., 1986, p. 5). The geology is predominantly limestone with raised plateaus and ridges and low-lying plains (Stafford et al., 2005, p. 15; Engbring et al., 1986, p. 5). Tinian lacks streams but has two small wetland areas, Hagoi Marsh and Marpo Swamp (Engbring et al., 1986, p. 5).

Fig. 5 Seasonal rainfall in the Mariana archipelago. Data extracted from Harris, I., Jones, P. D., Osborn, T. J. and Lister, D. H. (2014). Updated high-resolution grids of monthly climatic observations—CRU TS3.10: The Climatic Research Unit (CRU) Time Series (TS) Version 3.10 Dataset. *International Journal of Climatology* **34** (3), 623–642, doi: 10.1002/joc3711; updated from previous version of CRU TS3.xx (most recent use in CCKP: TS3.24). U.S. Fish and Wildlife Service, Pacific Islands Fish and Wildlife Office.

Saipan

Located approximately 3 mi (4.5 km) northeast of Tinian and 52 mi (83 km) south of Farallon de Medinilla, Saipan is the second largest of the Mariana archipelago, measuring 44 mi² (115 km²) with a peak elevation of 1555 ft. (474 m) on Mt. Tapochau (Mueller-Dombois and Fosberg, 1998, p. 256). Geologically, the island is comprised primarily of terraced limestone peaks and intrusions of exposed volcanic ridges and slopes (Mueller-Dombois and Fosberg, 1998, p. 256). Small streams occur on the volcanic portions of the island as well as numerous wetlands of various size in the coastal areas.

Farallon de Medinilla

Located approximately 52 mi (83 km) northeast of Saipan and 33 mi (53 km) south of Anatahan, Farallon de Medinilla (FDM) is a small, uninhabited, limestone and volcanic island measuring less than 1 mi² (3 km²) with a peak elevation of 1047 ft. (319 m) (Lusk et al., 2000, pp. 1; CNMI-SWARS, 2010, p. 6). The island is mostly flat, but ringed by steep sea cliffs which make access by boat difficult. The island was used as a bombing target and a bomb disposal site for over three decades by the US Navy, and as a result, much of FDM is rocky and barren with the exception of some grass and shrubs. Hydrology on the island consists of ephemeral seeps.

Anatahan

Located approximately 33 mi (53 km) northwest of FDM and 23 mi (37 km) south of Sarigan, Anatahan is an active volcanic island measuring 12 mi² (31 km²) in land area with a peak elevation of 2582 ft. (788 m) (Mueller-Dombois and Fosberg, 1998, p. 252; CNMI-SWARS, 2010, p. 6). Notable physical features of Anatahan include two active volcanoes with an east to west trending summit depression formed by overlapping summit craters (Berger et al., 2005, p. 11). The largest caldera measures 1.5 by 2 mi (2 by 3 km) wide. Between 2003 and 2008, Anatahan erupted several times, with the largest eruption occurring in 2008, covering the island with at least 6 ft. (2 m) of volcanic ash and destroying an estimated 98% of its forest and savanna habitats (Berger et al., 2005, p. 11; Kessler, 2011, p. 321, 323). Hydrology on the island consists of ephemeral streams and seeps.

Fig. 6 Typhoon tracks passing near the Mariana archipelago since from 1901 through 2018. Data extracted from Japan Meteorological Agency, (2019). <https://www.jma.go.jp/jma/indexe.html>—U.S. Fish and Wildlife Service, Pacific Islands Fish and Wildlife Office.

Sarigan

Located approximately 23 mi (37 km) northeast of Anatahan and 40 mi (64 km) south of Guguan, Sarigan is a roughly triangular-shaped, volcanic island measuring 2 mi² (5 km²) with a peak elevation of 1801 ft. (549 m) (CNMI-SWARS, 2010, p. 6). Sarigan consists of a low truncated volcanic cone with a 2460 ft. (750 m) wide summit crater containing a small ash cone. Other notable physical features of Sarigan include irregular shorelines with steep cliffs created by old lava flows (Berger et al., 2005, p. 12). Although currently uninhabited, the island is believed to have once been inhabited by the Chamorro people (Russell, 1998, p. 86). Hydrology on the island consists of ephemeral streams and seeps.

Guguan

Located approximately 19 mi (30 km) south of Alamagan and 40 mi (64 km) northeast of Sarigan, Guguan is an active volcanic island measuring a total of 2 mi² (4 km²) with a peak elevation of 988 ft. (301 m) (Ohba, 1994, p. 16). Its north side consists of an active volcano devoid of vegetation due to relatively recent activity and its south side consists of an older eroded volcano covered with dense native forest (Berger et al., 2005, p. 42; Amidon et al., 2011, p. 8). Other notable physical features of Guguan include steep cliffs along the shoreline and moist to wet ravines (Ohba, 1994, p. 16; Cruz et al., 2000, pp. 3–5, 9; Amidon et al., 2011, p. 8, 2017, pp. 20, 38). Hydrology on the island consists of ephemeral streams and seeps.

Alamagan

Located approximately 18 mi (29 km) north of Guguan and 30 mi (48 km) south of Pagan, Alamagan is an active volcanic island, measuring 4 mi² (11 km²) with a peak elevation of 2441 ft. (744 m) at Mt. Alamagan (Ohba, 1994, p. 16). Alamagan is the emergent summit of a large stratovolcano with a 1148 ft. (350 m) deep summit crater at the center of the island (Berger et al., 2005, p. 12). Most of the historically recent eruptions have been violently explosive (Berger et al., 2005, p. 12). Native forest occurs in mid-elevation ravines (Ohba, 1994, p. 16). Hydrology on the island consists of ephemeral streams and seeps.

Pagan

Located approximately 30 mi (48 km) north of Alamagan and 42 mi (68 km) south of Agrihan, Pagan is the fifth largest island in the Mariana archipelago and the largest of the northern islands with a total land area of 19 mi² (48 km²) (Ohba, 1994, p. 17). Pagan consists of four merged volcanoes, Mt. Pagan in the north, connected by a narrow isthmus to an unnamed complex of three older volcanoes in the south (Ohba, 1994, p. 17). The highest point on the island is Mt. Pagan, which rises 1870 ft. (570 m) above sea level. Mt. Pagan is among the most active volcanoes in the Mariana archipelago (Schils, 2010, p. 2). Mt. Pagan's last major eruption occurred in 1981 (Banks et al., 1981, p. 225); however, according to U.S. Geological Survey's Volcano Hazards Program, Mt. Pagan's most recent eruption occurred in 2012. Hydrology on the islands consists of two lakes on the flanks of Mt. Pagan and numerous ephemeral streams and seeps.

Agrihan

Located approximately 39 mi (63 km) north of Pagan and 64 mi (102 km) south of Asuncion, the island of Agrihan is an almost perfectly round, active volcanic cone (Ohba, 1994, p. 17) measuring 16.8 mi² (43.5 km²). With a peak elevation of 3166 ft. (965 m), it is the tallest island in the archipelago. Hydrology on the island consists of ephemeral streams and seeps.

Asuncion

Located approximately 62 mi (100 km) north of Agrihan and 23 mi (37 km) southeast of Maug, Asuncion is an active volcanic island measuring 3 mi² (7 km²) with a peak elevation of 2923 ft. (891 m) (Ohba, 1994, p. 18; Mueller-Dombois and Fosberg, 1998, p. 245). The long interval since Asuncion's last confirmed eruption in 1906, in conjunction with its high summit often enclosed by clouds, affords this cone-shaped island with densely forested slopes with diverse vegetation (Ohba, 1994, p. 18). Hydrology on the island consists of ephemeral streams and seeps.

Maug

Located approximately 24 mi (39 km) north of Asuncion and 43 mi (70 km) south of Uracas, Maug consists of three small volcanic islets, East Island, West Island, and North Island. The collective area of the three islets measures 0.8 mi² (2 km²) with a peak elevation of 745 ft. (227 m) on North Island (Ohba, 1994, p. 18; Mueller-Dombois and Fosberg, 1998, p. 244). The three islets are the emergent portions of a largely submerged volcano with a central lagoon (Ohba, 1994, p. 18; Mueller-Dombois and Fosberg, 1998, p. 244). Hydrology on these islets consists of ephemeral seeps.

Uracas

Located approximately 43 mi (70 km) south of Maug, Uracas (also known as Farallon de Pajaros), is the northernmost island of the Mariana archipelago. The island is an active volcano measuring 0.9 mi² (2 km²) with a peak elevation of 1180 ft. (334 m) (Ohba, 1994, p. 18). Hydrology on the island consists of ephemeral seeps.

Abstract

This article represents a status assessment of the Mariana Islands coastal ecotype, including the status, stressors, and future viability. The coastal ecotype in the Mariana Islands is composed of two sub-types: coastal strand and mangrove swamps. Coastal strand is present on portions of the perimeter of all islands in the archipelago but is more extensive on the older and larger southern islands (i.e., Guam, Rota, Tinian and Saipan), while mangrove swamps are limited to Guam and Saipan. Coastal strand and mangrove swamps are generally limited to a narrow zone above high tide and below the line of influence of shoreline processes such as periodic salt-water inundation, eroding winds, salt spray, and groundwater influx. Invasive species degrade and fragment coastal areas and disrupt mutualistic relationships among biota. Sea level rise and increased storm frequency exacerbate this. Typhoons, drought, sedimentation, erosion and pollution also degrade coastal systems.

Introduction

The 15 main islands and associated small islets of the Mariana archipelago hereby referred to as Marianas, stretch north to south for 890 km in the western Pacific Ocean. The archipelago extends from Uracas (also known as Farallón de Pájaros) located at 20.5°N, 144.9°E south to the island of Guam located at 13.4°N, 144.8°E; all are of volcanic origin. The older and larger islands in the south are composed of elevated coral limestone and weathered basalt (Mueller-Dombois and Fosberg, 1998). The vast majority of the land area is concentrated in these large southern islands, specifically Guam, Rota, Tinian and Saipan. The younger islands to the north are composed of black basalts and some have active volcanoes (Ohba, 1994). The tropical climate has little temperature variation (e.g., monthly averages are 24 °C–27 °C) and distinct wet (July–October) and dry (November–June) seasons (Mueller-Dombois and Fosberg, 1998). Precipitation averages 2000–2500 mm/year (Mueller-Dombois and Fosberg, 1998). This document will describe the terrestrial coastal ecotype of the Marianas with a focus on factors that have influenced the systems in the past and what to expect in the future.

Geology

The Marianas are of volcanic origin but their geology varies based on the age of the island. The older and generally larger islands in the south, from Guam to Farallon de Medinilla, contain extensive areas of uplifted limestone and have a terraced appearance with large plateaus and steep cliffs (Mueller-Dombois and Fosberg, 1998). The limestone substrate weathered over time to produce

shallow, fertile soils that are high in calcium (Donnegan et al., 2011). The younger northern islands, from Anatahan to Uracas, are cone-shaped stratovolcanoes (i.e., steep, many-layered volcanoes characterized by periodic, explosive eruptions) comprised mostly of hardened lava, tephra, and volcanic ash (Mueller-Dombois and Fosberg, 1998; Ohba, 1994). Some of the islands remain volcanically active with periodic, explosive eruptions (e.g., Uracas in 1967; Pagan in 1981; Anatahan in 2003) (Venzke, 2013). Most beaches are made of calcareous sand, composed of pulverized fragments of the skeletons or shells of corals, calcareous algae, foraminifera, and mollusks (Mueller-Dombois and Fosberg, 1998). Volcanic sand exists near the young volcanoes of the northern islands and a few river mouths in southern Guam (Mueller-Dombois and Fosberg, 1998). The coastal ecotype is heavily influenced by movement of sediments such as sand and silt that are transported by waves and currents from the ocean, wind and rainfall, and rivers, which flush sediment from upland areas (Maanan and Robin, 2015). Therefore, fluctuations in sediment transport, especially those related to excess erosion and/or deposition can result in functional changes in coastal habitats, including changes in species composition and distribution (Levin et al., 2011).

Coastal Ecotype Description

The Mariana coastal ecotype generally is limited to a narrow zone above the high-tide level and below the line of influence of shoreline processes such as periodic salt-water inundation, eroding wind, salt spray and movement of groundwater (Falanruw et al., 1989; Mueller-Dombois and Fosberg, 1998). These processes sculpt the bare sand, muddy sand, rocks, bench platforms (narrow erosional platform cut into limestone or volcanic rock) and/or karst (landscape formed by the dissolution of soluble limestone rock) that make up the substrate in coastal areas. The coastal ecotype is present along portions of the coastlines of all islands and islets in the Marianas (Amidon et al., 2017; Ohba, 1994).

In the Marianas, two vegetation communities are present in the coastal system: coastal strand and mangrove swamp. The flora of both tends to be halophytic and plants often have fleshy leaves; an adaptation to reduce evaporation accelerated by the direct sunlight and/or strong winds present in this system (Fosberg, 1960). Although the coastal ecotype is present on all islands and islets in the Marianas, it is more extensive on the older and larger islands in the south (i.e., Guam, Rota, Saipan, and Tinian). Mangroves are only present on Guam and Saipan (Amidon et al., 2017). On the southern islands, all coastal habitat makes up no more than 2% of any island area (Amidon and Reeves, 2018). Sea level variation, typhoon frequency, and coastal disturbance by humans are drivers of the distribution of the coastal ecotype (Fosberg, 1960). Features within the ocean (e.g., coral reefs) bordering one side of this ecotype help protect from storm surge and other erosional forces (Fig. 1).

The coastal strand is a community of flowering plants, creeping vines and salt-tolerant grasses and is found above the high-tide line and sometimes between other inland ecotypes such as atoll and limestone forest (Falanruw et al., 1989). Coastal strand vegetation is adapted to well-drained soils and exposed shoreline conditions that include salt water and spray, strong winds, and direct sunlight, which increase evaporation rates (Fosberg, 1960). Coastal strand species are well adapted to maximize pollination services via insects. Seeds are light and buoyant to be easily dispersed by wind, ocean currents, or carried on the plumage or inside the gut of birds; contributing to wide distributions (Heatwole et al., 1981). This strategy also enhances the ability to recolonize suitable substrate after catastrophic or stochastic events (Table 1).

Mangrove swamps (mangroves) are limited to Guam and Saipan and found in estuarine-tidal flats and in coastal swamps at the mouths of small rivers (Moore et al., 1977; Stone, 1970). Mangroves provide sediment stabilization in estuaries, protection from storms, maintenance of water quality and spawning grounds and nutrients for a variety of fish and shellfish (Raulerson and

Table 1 Common plant species found in the coastal strand subtype of the coastal system in the Mariana archipelago (Stone, 1970; Raulerson and Rinehart, 1991; Asakura et al., 1994; Mueller-Dombois and Fosberg, 1998).

Species name	Chamorro or common name	Vegetation type
<i>Barringtonia asiatica</i>	Fishkill tree, putting, ghuul	Tree
<i>Bikkia tetrandra</i>	Torchwood, gausali	Shrub
<i>Casuarina equisetifolia</i>	Ironwood, gagu, gago	Tree
<i>Cassytha filiformis</i>	Love vine	Vine
<i>Cordia subcordata</i>	Niyoron, aliw	Tree
<i>Heliotropium foertherianum</i>	Velvet leaf, hunik, hunek, hunig, tchel	Tree
<i>Hibiscus tiliaceus</i>	Sea-hibiscus, corkwood, pago	Tree
<i>Hernandia nymphaeifolia</i>	Lantern tree	Tree
<i>Ipomoea pes-caprae</i>	Alaahi tasi, beach morning glory	Vine
<i>Lepturus repens</i>	Bunchgrass	Grass
<i>Mammea odorata</i>	Chapok, chopag	Tree
<i>Ochrosia mariannensis</i>	Lipstick tree, lengit	Tree
<i>Pandanus tectorius</i>	Kafu, fatsao	Tree
<i>Pemphis acidula</i>	Nigas, engi	Shrub
<i>Scaevola taccada</i>	Half flower, fan flower, nanaso, lanasa, liat	Small tree/shrub
<i>Sesuvium portulacastrum</i>	Chara	Herb
<i>Sporobolus virginicus</i>	Seashore rushgrass	Grass
<i>Thuarea involuta</i>	Las-aga, kuroiwa grass	Grass
<i>Thespesia populnea</i>	Rosewood	Small tree
<i>Vigna marina</i>	Beach pea	Vine

Table 2 Primary flora species found in the mangrove swamp subtype of the coastal system in the Mariana Islands archipelago (Stone, 1970; Falanruw et al., 1989).

Species name	Chamorro or common name	Vegetation type
<i>Acrostichum aureum</i>	Langayao	Fern
<i>Avicennia marina</i>	Gray mangrove, white mangrove	Tree
<i>Acrostichum aureum</i>	Mangrove fern, golden leather fern	Fern
<i>Barringtonia racemosa</i>	Langasát or langaasag	Tree
<i>Bruguiera gymnorrhiza</i>	Manglan lahi	Tree
<i>Heritiera littoralis</i>	Ufa-halomtano	Tree
<i>Hibiscus tiliaceus</i>	Sea hibiscus	Shrub
<i>Lumnitzera littorea</i>	Nana or red-flowered mangrove	Tree
<i>Nypa fruticans</i>	Nipa or mangrove palm	Tree
<i>Rhizophora apiculata</i>	Mangle hembra	Tree
<i>Rhizophora mucronata</i>	Red mangrove	Tree
<i>Rhizophora stylosa</i>	Stilted mangrove	Tree
<i>Xylocarpus granatum</i>	Mangrove cannonball	Tree
<i>Xylocarpus moluccensis</i>	Mangrove cannonball	Tree

Rinehart, 1991; Woodroffe, 1987; Selvam, 2007). In the Marianas, the mangrove swamp subtype has a fraction of species compared to mangroves elsewhere in the tropics (Fosberg, 1960); however, there is evidence that they are similarly productive as a function of detritus per unit area (Woodroffe, 1987). The seeds of the mangroves are torpedo-shaped propagules allowing them to either float to new habitat or establish in the water or mud beneath parent trees to create dense mangrove forests (Fosberg, 1960) (Table 2).

The viability of coastal strand and mangroves depends on maintaining multiple and distributed locations (redundant) of sufficient quality and size (resilient) with species richness and genetic diversity to be maintained across its ecological environment (representative) over time. The phrase “ecologically healthy” refers to functions affecting biodiversity, productivity, biochemical cycles, and evolutionary processes that are linked to the climatic and geologic conditions in the region (Borja et al., 2008). The ecologically healthy, or viable, coastal ecotype that existed throughout the Marianas prior to human contact likely maintained natural connections between system components. Native biota that was historically characteristic of Mariana coastal strand and mangroves filled environmental niches necessary to sustain the habitat (Fig. 2).

The coastal ecotype occurs in a narrow band around portions of islands. Although it was likely more abundant and diverse before human arrival and subsequent alteration and development of coastal areas, the coastal ecotype is still common and considered moderately redundant. The mangrove subtype has a more constricted range and only occurs on two islands in the archipelago (i.e., Guam and Saipan), thus this subtype has low redundancy.

Fig. 2 Example of a mangrove swamp with aerial roots visible at Cabras Marina, Guam. Photo: USFWS.

Resilience is defined as the amount of disturbance that the system can absorb without a change in structure and composition (Carpenter et al., 2001). Disturbance in coastal strand and mangrove habitats include natural forces such as typhoons and sea level change. Due to well drained soils in the coastal strand, salt water tolerance, and highly adapted flora and fauna (avian dispersal, floating seeds, and root systems) in coastal strand and mangroves, “healthy” coastal habitats have an increased capacity (high resiliency) to recover from natural stochastic events.

Representation relates to the variety of system types and variety of species within subtypes. The coastal strand subtype is relatively speciose and occurs on a wider range of islands within the archipelago compared to the mangrove subtype. The mangrove subtype’s restricted range means it is more poorly represented than coastal strand.

The primary driving factor for maintaining representation and redundancy for coastal strand and mangroves is related to dispersal and connectivity. Connectivity refers to the ability of plants and animals to move between habitat patches on the landscape (Tischendorf and Fahrig, 2000). Wind and water, specifically the ocean, is essential for dispersal to distant sites, though some propagules utilize birds for natural dispersal in aquatic systems. Seabirds and migratory birds which may consume or otherwise carry propagules, contribute to connectivity between coastal habitats at small to large scales (i.e., regional to inter-continental) while transiting between feeding, breeding, and non-breeding areas (Buelow and Sheaves, 2015).

Pre-Human Condition

Information about native vegetation in the Marianas prior to the arrival of humans is limited. Accurate descriptions of coastal vegetation communities during this period requires information from the fossil record and observations of the composition of relatively undisturbed, intact coastal systems. Prior to human colonization, the coastal system in the Marianas was present on every island in the archipelago (Fosberg, 1960; Ohba, 1994) and was heavily influenced by changes in sea level (Woodroffe, 1987). Pacific sea level declines during the late Holocene caused profound coastline changes. Around 3000–4000 years ago, the drop in sea level exposed extensive low tide platforms. Erosion, typhoons, and volcanic eruptions also influenced the physical coastline.

Prior to human colonization, coastal strand and mangrove swamps were more speciose overall and thus more resilient. The dominant species varied across the archipelago as dictated by geomorphology. Similar to today, mangrove swamps in the Marianas were less speciose relative to coastal strand (Fosberg, 1960). Thus, prior to human contact, the Marianas coastal ecotype was highly resilient and had medium (strand) and low (mangroves) levels of redundancy and representation (Table 3). As we see today, coastal

Table 3 Levels of resiliency, redundancy, and representation for coastal strand and mangrove swamp subtypes of the coastal ecotype that existed in the Mariana Island Archipelago prior to human contact.

<i>Habitat type</i>	<i>Resiliency</i>	<i>Redundancy</i>	<i>Representation</i>
Coastal strand	High	Medium	Medium
Mangroves	High	Low	Low

strand was diverse and widespread across the islands, and was better represented and had greater redundancy than the mangrove subtype, which had lower species diversity and was limited in distribution to Guam and Saipan (Fosberg, 1960; Falanruw et al., 1989).

Current Condition

Rapid human settlement of the central Pacific including the Marianas 2500–3500 years ago (Nunn, 1990) caused widespread alteration of coastal areas (Athens and Ward, 2004). The development of coastal plains as sea level fell since the last interglacial period may have made coastlines more attractive for human settlers. The human occupation of the Marianas resulted in coastal land use, development and accidental or intentional introduction of invasive species, which altered much of the vegetation across the islands so drastically that pristine habitats are rare (Spoehr, 1957; Athens and Ward, 2004). Over time, the distribution and species composition of coastal strand and mangroves changed substantially to include a variety of introduced biota that are capable of affecting species distribution, diversity and abundance (Reddy, 2011). Invasive plants [e.g., *Cuscuta campestris* (dodder) and *Antigonon leptopus* (chain of love)] and animals [e.g., feral ungulates, *Rattus* spp., invasive ants (Family Formicidae)] are present in coastal areas and can have profound effects on ecosystems (Table 4) (Kessler, 2011; Raulerson and Rinehart, 1991; Wiewel et al., 2009).

Some of the more dominant coastal strand species today include: *Pemphis acidula* (often pitted in limestone of windward coasts), *Heliotropium foertherianum* and *Casuarina equisetifolia*, which are found in loamy areas; and *Scaevola taccada* and *Ipomoea pes-caprae* which are found on sandy beaches (Table 1). Coconut palms (*Cocos nucifera*) were present in sediment cores over 4000 years ago prior to human colonization so are native to the Marianas (Athens and Ward, 2004). Coconut palms have gradually become more common as they were planted widely and many islands now contain nearly monotypic stands (Asakura et al., 1994). In many areas, native species still dominate coastal strand, primarily because the abiotic conditions (i.e., salt spray and inundation, wind and sun exposure) are harsh and limit colonization by other species.

In southern Guam, there was likely an increase of mangrove vegetation within the last 1000 years based on pollen cores in the area (Amesbury, 1999). Currently the largest concentrations exist along the eastern shores of Apra Harbor and smaller areas in Merizo and Inarajan. Guam's mangroves are dominated by *Rhizophora apiculata* but are composed of a variety of species that existed

Table 4 Primary invasive species in the Marianas coastal habitats.

Common name	Scientific name	Primary species affected	How invasive affects the ecotype	Where present	References
Ants	<i>Anoplolepis gracilipes</i> , <i>Wasmannia auropunctata</i>	Prey on native fauna, affect plant distribution via mutualisms and direct seed predation	Changes in distribution, abundance and diversity of biota	Pagan, Guam	Plentovich et al. (2018), Raymundo and Miller (2012), and Wetterer and Porter (2003)
Brown tree snake (BTS)	<i>Boiga irregularis</i>	Prey on fauna including birds and reptiles	Absence of bird dispersers, so reduced vegetation dispersal and reduced germination success	Guam	Savidge (1987) and Rodda and Savidge (2007)
Coconut rhinoceros beetle (CRB)	<i>Oryctes thinocerosrhinoveros</i>	Coconut palms	Loss of vegetation	Guam Rota	CNAS (2016) and Marshall and Moore (2016)
Vines (Ivy Gourd, Bitter Melon, Mile-a-Minute, Mikania, Woodrose, Chain of Love)	<i>Coccinia grandis</i> , <i>Momordica charantia</i> , <i>Mikania scandens</i> , <i>Mikania micrantha</i> , <i>Merremia tuberosa</i> , <i>Antigonon leptopus</i>	Native vegetation	Aggressively block sunlight and compete for water with native plants, smothering them altogether	Saipan, Tinian, Guam	PIER (2018)
Ungulates (goats, pigs, deer)	<i>Capra hircus</i> , <i>Sus scrofa</i> , <i>Rusa marianna</i>	Native vegetation	Dig up soils, facilitating erosion and sedimentation input, prevent survival of seedlings, consume or otherwise destroy natural resources	Guam, Aguiguan, Tinian, Rota, Anatahan, Pagan, Agrigan	Kessler (2011), Liske-Clark (2015) and Rubinoff and Holland (2018)
Rodents	<i>Mus musculus</i> , <i>Rattus</i> . Cf. <i>diardii</i> , <i>R. exulens</i> , <i>R. norvegicus</i> , <i>R. rattus</i> , <i>Suncus murinus</i>	Native biota; prey on native and nonnative biota, including birds and plant	Depredate and compete with native fauna, impede plant survival by eating seeds	All Islands	Steadman (1999), Liske-Clark (2015) and Wiewel et al. (2009)

historically. *Rhizophora* no longer occurs on Saipan; instead it has been replaced by another species in the Rhizophoraceae, *Bruguiera gymnorrhiza* (Moore et al., 1977). *Heritiera littoralis* and *Xylocarpus moluccensis* are also common in Saipan's mangroves (Falanruw et al., 1989).

Currently, coastal habitat makes up less than 2% of any island within the Marianas (Amidon and Reeves, 2018). Coastal areas were mapped on the larger, older southern islands where it composes 953 acres on Guam, 373 acres on Rota, 468 acres on Saipan, and 636 on Tinian. Coastal areas are not mapped on most of the northern islands. Of the 373 acres of coastal habitat on Guam, mangrove swamps account for 182 acres. Of the 468 acres of coastal habitat on Saipan, mangroves only account for 2 acres that occur near the American Memorial Park. The stressors below affect the ecotypes resilience, redundancy and representation.

Stressors

Climate Change

Predicted climate changes such as increased precipitation, sea level rise, and increased typhoon intensity will have significant effects on coastal systems in the Marianas. Global temperatures have increased over the past century and the rate accelerated in the mid-20th century (Pachauri et al., 2014). These increased temperatures correlate with carbon dioxide emissions, which have increased more since 1970 than in prior periods (Pachauri et al., 2014). The oceans are absorbing more than 80% of the heat added to the Earth's climate system (Griggs and Noguer, 2002) causing average global ocean temperatures to increase and thermal expansion of the sea. Thermal expansion combined with melting ice (e.g., alpine glaciers, ice-sheets and ice caps) will result in global sea level changes. Some coastal systems may be able to migrate inland as sea level rises if there is time and space; however, this may not be possible where heavy coastline development exists. Typhoons cause significant disturbance in these areas and increased intensity and frequency will reduce recovery time and will likely have significant negative effects on these systems in the foreseeable future.

Development

Economic development has and continues to affect the coastal ecotype in the Marianas. Coastal development includes the construction of buildings [e.g., hotels, residential homes, and facilities associated with providing necessities (e.g., fresh water, sewage treatment, etc.) to these buildings], marine structures (e.g., bulkheads, seawalls, breakwaters, jetties, and piers), recreational sites (e.g., parks, lookouts, harbors, etc.), and sand hardening that has occurred as a result of development. These structures can alter the substrate, hydrology, and resources required by native coastal communities (Agardy and Alder, 2005). Additionally, development of coastal areas increases the potential for invasion by nonnative species (see section **Invasive Species** below). For example, many invasive species such as invasive ants and brown tree snake can be transported in building materials, equipment, and soil (Hulme, 2009). Coastal development contributes to fragmentation of naturally occurring communities. The fragmentation of ecotypes decreases the total area and reduces the abundance, diversity and composition of communities found in the system, thereby reducing the system's resiliency, or ability to withstand stochastic events including typhoons and storm surge.

Development across the Marianas is correlated with population size. Guam and Saipan are the most populous and developed islands and therefore face the largest threat from development in the foreseeable future (Fig. 3). Coastal habitat on other islands,

Fig. 3 Coastal development along the western coast of Saipan near the town of Garapan. Photo: R. Walker.

including Tinian and Rota also experienced a decrease in total area due to development projects such as casinos and/or upscale hotels and military training facilities (Pacific Engineering Group, and Services, and Chris Hart, and Partners, Inc., 2018). World War II caused substantial impacts to natural resources of the Marianas. Post World War II, there was a large increase in development, including rebuilding Apra Harbor in Guam. Military operations and bases have continued to expand since that time and include the use of one of the northern islands, Farallon de Medinilla, for training exercises (Guampedia, 2018).

Tourism also contributes to development and thus a loss of coastal systems. In 2003, Guam and the Commonwealth of the Northern Mariana Islands (CNMI) were identified as two of thirteen most developed small island international destinations characterized by visitor density (McElroy, 2003). The inhospitable coastal geomorphology and topography naturally limit development in some areas.

Invasive Species

Oceanic islands such as the Marianas are known to be especially vulnerable to species introductions, which have caused significant, detrimental effects in coastal systems (Table 4) (Vitousek, 1988). Invasive generalist predators such as rats and invasive ants cause cascading effects in ecosystems (O'Dowd et al., 2003; Wiewel et al., 2009). Rats (*Rattus* sp.), which are not native to the Marianas, have detrimental effects in coastal systems by directly (e.g., eating plant seeds and flowers) and indirectly (e.g., reducing populations of other seed predators and dispersers such as birds and invertebrates) altering the distribution, diversity and abundance of plants (Rankin et al., 2018; Steadman, 1999; Wiewel et al., 2009). Currently three or more rat species are present in the archipelago (Wiewel et al., 2009). Invasive ants are another generalist predator that threatens coastal systems by displacing native invertebrates and vertebrates via predation and/or competition (O'Dowd et al., 2003; Plentovich et al., 2018; Wetterer and Porter, 2003). Additionally, ants farm sap-sucking insects (e.g., scales and aphids), which can cause defoliation of plant species. Little fire ant is currently only present on Guam, but its small size allows it to spread easily in soils, especially those in potted plants (Raymundo and Miller, 2012). The yellow crazy ant is present on Pagan and is spread primarily in cargo and soils. Little fire ant and yellow crazy ants pose significant risks to biodiversity in coastal areas in the Marianas.

In addition to the species above, the brown tree snake, other invasive invertebrates (e.g., coconut rhinoceros beetle), feral ungulates, and a variety of invasive plants cause significant and catastrophic degradation in coastal systems (Table 4). Biosecurity measures and monitoring are not adequate to prevent spread, or to determine the true extent of invasive species at this time. In addition, other invasive species are likely present but their presence and effects have not yet been determined.

Pollution

Various pollutants including oils, untreated sewage, human-generated trash, Polychlorinated biphenyls (PCBs), heavy metals, plastic marine debris and sediments negatively affect coastal systems in the Marianas, especially the populated southern islands. Oil from spills, run-off, and land-based waste adversely affects aquatic organisms at all trophic levels including primary producers, echinoderms, mollusks and seabirds (Li et al., 2016). Sewage run-off is a significant problem in the southern islands where there is a link between sewage-derived nitrogen pollution and coral disease severity (Redding et al., 2013). PCBs and heavy metals are present in harbor sediments and marine organisms on Guam and interfere with normal development and behavior (Denton et al., 2005, 2006). Marine debris including discarded fishing gear and plastics is widespread in the Marianas and has negative effects on coastal systems. Plastics form a thin layer on shells, sand and other debris and sink in water resulting in the inability to transfer nutrients and gases between water and sediments. Fauna using coastal systems, like sea turtles and seabirds, can become entangled in and ingest plastic and other debris causing harm and sometimes death (Wilcox et al., 2015).

Sedimentation/Erosion

Excess sediment deposition and erosion can change native plant and animal communities by destabilizing substrates, damaging or destroying individual plants, and altering hydrological patterns. In Guam, limited vegetation due to wildfires results in an increase in erosion and sedimentation, negatively affecting downstream areas and coral reefs (Golabi et al., 2005). These coral reefs provide coastal protection by dissipating wave energy, which could damage coastal areas (Pickard et al., 1990). Excess sediment from fires, vegetation clearing, and erosion upland of the coast overload coastal vegetation and fill stream estuaries where mangroves may be growing (Golabi et al., 2005).

Typhoons

The Marianas lie in a typhoon belt and regularly experience typhoons. Typhoons cause variety of impacts to vegetation including pruned or downed vegetation from intense wind, defoliation and damage from wind, heavy rain and salt spray, and mortality by salt-water inundation in low-lying areas (Fosberg, 1960; Kerr, 2000).

The stressors described above decrease ecotype range and diversity, and increase fragmentation relative to its prehuman condition. Climate change, development, erosion, and increased typhoon frequency contributed to permanent losses of native coastal communities and increased fragmentation, which has reduced resilience and redundancy of both the coastal strand and mangrove subtypes. Loss of mutualistic relationships and declines and/or extirpations of native species associated with species introductions

reduced species diversity and therefore representation in both subtypes. This will be exacerbated as the system degrades and becomes more and more vulnerable to species introduction. Species declines, permanent loss of habitat due to development and climate change, and the break-down of mutualistic relationships means the coastal system may not be able to recover and future restoration options are limited. Decreases in resiliency, representation, and redundancy translate into a loss of viability for the coastal ecotype.

Conservation Opportunities

Impacts from stressors may be addressed through laws and regulations, land protections, education, outreach, and/or various management approaches such as on-the-ground management (e.g., predator and invasive species control). These approaches are implemented by government agencies (territory, commonwealth and federal), private organizations or individuals, and non-governmental organizations. Given that land ownership of this system is spread among these parties, partnerships are sometimes formed to manage the system collectively. The following conservation efforts provide direct and indirect benefits to the coastal habitat as well as other habitats and ecosystems.

Guam Coastal and Estuarine Land Conservation Program Plan

A draft 2008 Guam Coastal and Estuarine Land Conservation Program Plan was written with the intention to protect important coastal and estuarine areas that have significant conservation and ecological values with consideration given to the degree of threat of loss, ecological significance and potential for effective management ([Guam Coastal Management Program, 2008](#)).

Cleanup Activities

Cleanup activities are limited to the Guam, Rota, Saipan and Tinian and are typically volunteer based. Both Guam and the CNMI participate in the annual Ocean Conservancy's annual beach clean-up in September. Volunteers collect garbage off beaches, strand, and other coastal areas. In 2014, the CNMI event had nearly 1400 volunteers collect over 19,600 pounds of trash. These efforts engage the public to care about local resources and improve the health of the coastal habitat ([Micronesia Challenge, 2018](#)).

The Guam National Wildlife Refuge hosts a beach clean-up on the first Saturday of each month to remove debris from the Refuge's coastline. In fiscal year 2017, over 195 volunteers removed 1304 pounds of trash from the beaches ([United States Fish and Wildlife Service, 2018](#)). The National Park Service hosts beach clean-ups on the second Saturday of each month at both its Guam and Saipan locations (<https://www.nps.gov>).

Erosion Control

Efforts to combat erosion have increased recently as a way to protect coral reefs and may indirectly improve the coastal habitat. Public education campaigns have periodically been enacted to educate outdoor enthusiasts of how their activities affect habitat. National Oceanic and Atmospheric Administration (NOAA) Coastal Management Program has committed resources to the conservation of Guam's Manell-Geus Habitat Focus Area by replanting upland areas and restoring native vegetation to the lower riverine areas. By focusing on stopping erosion in savanna areas, NOAA hopes to improve the health of the coastal habitat and ocean waters downstream. Long-term plans include establishment of a monitoring plan to detect changes in the health of the mangrove forests in this area ([National Oceanic and Atmospheric Administration \(NOAA\), 2014](#)).

On Saipan, the Laolao Bay watershed is being improved by revegetating badlands damaged by fire and illegal land clearings as well as conducting grassroots education campaigns. The intent is to restore the upland vegetation, which would result in reduced sediment in the watershed, ultimately improving the quality of coastal habitat and marine waters.

Invasive Species Management and Control Activities

Conservation efforts to control, interdict and mitigate the effects of terrestrial invasive species in the Marianas are limited. With a few exceptions (e.g., Brown tree snake and Coconut Rhinoceros beetle), the effects and extent of invasions are not well studied. Prevention of invasive species through biosecurity measures is essential in limiting risk to habitats and species of the Marianas. Both the CNMI and Guam have biosecurity mechanisms as part of their overall port programs. A major biosecurity focus within the Marianas is preventing the spread of brown tree snake (BTS) to the CNMI from Guam. In this regard, federal agencies support local capacity in Guam and the CNMI. On Guam, there are extensive efforts to keep BTS out of the transportation chain, effectively reducing the potential for BTS to be accidentally transported from the island. In the CNMI, there are efforts to ensure that high-risk cargo and craft arriving from Guam are inspected to reduce risks of BTS accidentally arriving and establishing.

The University of Guam and the Northern Marianas College provide research and extension services to support invasive species management, as do the various soil and water conservation districts. Activities include Coconut Rhinoceros Beetle monitoring and management and research programs. Similarly, both the CNMI and Guam have government offices and staff that support pest species and natural resource management and conservation and restoration efforts. The U.S. Department of Defense has active

natural resource programs on military lands, which included full time staff and various projects such as BTS management, feral ungulate control, habitat restoration and fencing control.

The Coconut Rhinoceros Beetle was first detected on Guam 2007 in an area totaling less than 1000 acres and eradication was attempted but failed. The Guam Coconut Rhinoceros Beetle Eradication Project was a joint effort involving the U.S. Department of Agriculture, the Guam Department of Agriculture and the University of Guam and U.S. Forest Service. Quarantine, biocontrol, sanitation, trapping, and chemical control of Coconut Rhinoceros Beetle were used unsuccessfully and the species is now found throughout Guam (A. Moore personal Communication 5/17/2018).

The National Park Service conducts vegetation management and has partnered with U.S. Fish and Wildlife Service on Guam on a project (Guam Recovery Actions for the Mariana eight-spot butterfly, tree snails, and a rare vine) to translocate species into the national park.

Interactions of Stressors, Conservation Actions, Protected Designations and Laws and Regulations

Of the stressors described above, the two most significant drivers of the current condition of coastal systems are (1) conversion/fragmentation of land due to development, and (2) the ongoing effects of invasive species. These stressors, which reduce resiliency, representation, and redundancy in the coastal system, are significant and ongoing, act in concert with other stressors, and are expected to continue or increase in magnitude and intensity into the future without effective management actions. Although laws, regulations, land protection, and conservation actions benefit coastal systems, these protections have not prevented an overall decline in native coastal systems.

The rate of native coastal system decline is highest on those islands with the largest human population (i.e., Guam and Saipan). Development within coastal systems is concentrated in Guam around Tumon Bay, Hagatna, and Apra Harbor and in Saipan in Garapan and Chalan Kanoa (Figs. 3 and 4). The plant and animal species found here have experienced reductions in numbers of populations and individuals and development contributes to fragmentation thus decreasing habitat connectivity. Mangroves have had additional protection through legislation and therefore have not faced similar threats from development. Throughout the archipelago, increased levels of restoration and conservation efforts such as invasive species management, restoration of badlands, and a reduction in the level of development have the potential to maintain the current native status or even reverse ongoing degradation occurring for these habitats.

Future Scenarios

The condition of the Marianas coastal ecotype in the foreseeable future is based on potential changes in three conservation management parameters (CMPs). These conservation parameters capture the social and legal mechanisms under which natural resource conservation is carried out. The CMPs are as follows:

- (1) *Conservation Values*: stakeholder involvement and public opinion determine the formulation, implementation and funding of natural resource conservation within laws and development plans.
- (2) *Laws and Biosecurity*: national, state, county, and city laws and regulations are the means by which natural resource conservation and biosecurity are supported and implemented. (e.g., hunting regulations, Clean Water Act, Endangered Species Act, and local laws, etc.).
- (3) *Development or Conservation Planning*: national, state, county, city, and private development plans or conservation plans define specific actions that result in losses or gains in natural resource conservation and biosecurity (impacts are only realized at the time of implementation).

These conservation management parameters are critical factors that drive the direction and magnitude of natural resource conservation, and determine foreseeable future scenarios. The year 2035 is the extent of the “foreseeable future,” and is based on the projected divergence of IPCC Representative Concentration Pathway (RCP) climate change scenarios (van Vuuren et al., 2011a,b). The four foreseeable future scenarios considered in this habitat assessment are:

Future Scenario One

Scenario One is considered the most likely future scenario, and serves as a “baseline.” There is no change in the implementation of the three CMPs between 2018 and 2035. A continuing current rate of change in land cover through this foreseeable future results in a slow but continuous change in the habitat. An expanding human population and increased development and general land use on all inhabited islands is anticipated (Table 5), and therefore habitat stressors are expected to increase at a small annual rate. The largest increases in development are expected on Saipan and Guam, where the largest human populations reside, with smaller increases on Rota and Tinian (Table 5). On average, the percentage of land developed for residential, commercial, and agricultural purposes within 100 m of the coastline on the four southern islands is expected to increase by 3% from 2016 to 2035.

The rate of sea level rise in relation to increased global temperatures has risen from about 0.1 in. (2.5 mm) per year in the 1990s to about 0.13 in. (3.4 mm) per year today (Legeais et al., 2018). As these trends continue, it is not likely to result in discernible changes to coastal communities within the Marianas in the next 15 years. Climate related stressors, such as drought and increased storm strength will further stress and degrade communities.

Fig. 4 Developed areas on Guam and Saipan defined as highly influenced by continuous human activities (e.g., impermeable human-made surfaces, landscaped areas, active cropland areas, roads, towns, parks, golf courses, airstrips, and military facilities, [Reeves and Amidon, 2018](#)).

Table 5 Current and future (2035) estimates of acreages of land classified as developed within the coastal zones (≤ 100 m from coastline) of the four main inhabited Mariana Islands.

<i>Island</i>	<i>Current^a</i>	<i>2035</i>	<i>Change</i>
Guam	455 (23.5%)	496 (25.7%)	+ 41 (2.2%)
Rota	37 (7.3%)	43 (8.6%)	+ 6 (1.3%)
Tinian	25 (4.5%)	31 (5.6%)	+ 6 (1.1%)
Saipan	173 (22.6%)	231 (30.1%)	+ 58 (7.5%)

All acreages are in hectares.

^aEstimates for Guam, Tinian, and Saipan are 2016 and Rota is 2014.

Data from Amidon F and Reeves M (2018) *Mariana Islands rates of change*. Technical Report 13. Honolulu, HI: U.S. Fish and Wildlife Service, Pacific Islands Fish and Wildlife Office.

Based on the analysis of the status quo scenario, we expect species declines, permanent loss, degradation and fragmentation of the coastal system due to development, invasive species spread and climate change, and continued loss and disruptions of mutualistic relationships. The coastal strand will be more directly affected by development than mangroves. Both subtypes will be less able to recover from stochastic events (i.e., less resilient), less speciose and diverse (i.e., less represented), and less represented across the landscape.

Future Scenario Two

Under Scenario Two, conservation agencies and stakeholders work with increased but limited resources to slow or stop the degradation of landscape areas. Although there is an expanding human population, development is not expected to increase substantially. A slightly improved biosecurity effort will reduce the rate of introduction of new invasive species and plant diseases but increases in the number and range of invasive species are still expected. Highly destructive invasive species, such as ungulates, rats, yellow crazy ant, little fire ant and coconut rhinoceros beetle are likely to persist or expand along coastlines where they will depredate, displace or degrade the coastal system. The slight improvement of natural resource conservation could result in the increased stewardship and protection of coastal areas. This could expand and protect more coastal systems potentially increasing their resilience to stochastic events and perturbations. The small increase in the CMPs associated with conservation planning and conservation values will not prevent, mitigate, or reverse the impacts of climate change-related stressors and is not expected to greatly alter wildfire frequency and intensity.

Future Scenario Three

Under Scenario Three, all natural resource management actions in the CMPs are set aside in deference to land use for economic development. An expanding human population requires increased land use for agriculture and development with no encumbrance from natural resource management. Biosecurity controls are significantly weakened leading to an increase in the number and spread of invasive species and new plant diseases. Combined together, these factors will result in substantial increases in wildfire frequency. The substantial loss of CMP supported conservation may locally aggravate the impacts of climate change-related stressors. Under this scenario, the coastal system will decline substantially in extent, quality and function through the foreseeable future. Already fragmented coastal vegetation will be completely lost. Areas that cannot support development become the only areas of free-living native species.

Future Scenario Four

Under Scenario Four an overt and robust, active, ongoing effort is made to engage partners and stakeholders in identifying and prioritizing landscape areas needed for the conservation of native habitats and ecosystems, and to actively restore and expand these habitats and ecosystems. Active and well-supported natural resource management begins to restore and expand these habitats and ecosystems. The needs of an expanding human population are addressed through more efficient land use governance based on redevelopment rather than development of undeveloped areas. Substantially improved biosecurity regulations decrease the rate of introductions of invasive species and plant diseases. Established invasive species will continue to spread but at a decreased rate relative to previous scenarios. These improved land management actions result in decreased wildfire frequency and extent. The substantial increase in CMP supported conservation may locally mitigate the effects of climate change-related stressors, but climate-related changes are expected in the near future. The coastal subtypes would be larger and less fragmented and could potentially disperse naturally into new areas. The larger and relatively intact systems would be more resilient to perturbations, better represented in term of species diversity and more redundant across the landscape relative to previous scenarios.

Abstract

The Galápagos Islands are a living laboratory for evolutionary biologists, biogeographers and ecologists. Many of the organisms floated or flew to the islands subsequently radiated into groups of endemic species, thereby increasing the biodiversity of the islands. But the Galápagos biota are an odd mixture of plants and animals, with many reptiles, but no amphibians; many bird species, but almost no mammals. The peculiarities of the Galápagos wildlife intrigued the young Charles Darwin, starting him on an intellectual journey that eventually produced his theory of survival of the fittest and evolution. The colonization of the islands by humans brought ecological disturbances of ever-increasing intensity until the Ecuadoran government began to take steps to ensure conservation of the islands' unique biota. The focus of much of the current conservation efforts is the prevention of the entry and spread of invasive species, both on land and in the sea.

Introduction

The Galápagos Islands include 19 islands and more than 42 islets. The total land surface of the archipelago adds up to about 8000 km². The islands straddle the Equator, extending north and south of this by about 1° of latitude. Located approximately 1000 km west of the South American mainland, the islands range from about 89–92°W longitude. Stretching over a 320-km diameter, the Galápagos Islands encompass 50,000 km² of ocean surface. The islands are perched atop an oceanic plateau called the Galápagos Platform. The ocean waters over the platform are relatively shallow, with depths of 360–900 m.

The [World Wildlife Fund \(2019\)](#) categorizes the Galápagos as Neotropical desert and xeric shrubland, as summarized below. The climate of the Galápagos varies little between islands. Seasonal differences are largely the result of the effects of multiple water currents. The 'misty' season lasts from about May to December, and results from the effects of the cold Humboldt Current (a cold, low-salinity ocean current that flows north along the western coast of South America, then arcs westward past the Galápagos Islands). This season is characterized by cool temperatures, mist and drizzle known as "gaura" that accumulates on the highlands of larger islands. The hot and wet season prevails from about December to May, under the influence of the warm Cromwell or Panama current. This season is characterized by heavier rainfall and warmer temperatures with March reaching as high as 30 °C with the islands receiving as much as 80 mm of rainfall.

A major driver of Galápagos climate is the periodic occurrence of El Niño events. On average, El Niño events affect the central Pacific region every 2–7 years. During El Niño years, the upwelling of the cold Humboldt Current is overwhelmed by strong warm water currents. The Humboldt Current normally provides nutrient rich waters with plankton that are the basis for the Galápagos marine food chain. El Niño events have strong negative effects on the birds, reptiles and mammals that rely on the marine environment for food, because the warm waters are much less productive. Although marine-dependent creatures suffer losses during El Niño years, land-based organisms often thrive, as increased rainfall supports unusually rich growth of vegetation.

The Galápagos archipelago is best known for its large array of endemic species. These plants, invertebrates and vertebrate species have evolved over time due to isolated island life. Endemism rates are high in all groups of organisms on these islands from lichens, flowering plants, insects and land snails to finches, giant tortoises, iguanas and rats.

Human History of the Islands

The Galápagos Islands were apparently not discovered by native South Americans in prehistoric times. The first known landing on the Galápagos was by Friar Tomás de Berlanga (1487–1551) who was a Spanish priest who traveled to the New World and eventually became the fourth Bishop of Panama (Fig. 1). In 1535, he was on route to Peru to settle a dispute between Francisco Pizarro and Diego de Almagro over division of conquered Inca territory. His ship was becalmed off the coast of northern South America, and strong currents carried him out to the Galápagos Islands where he landed on March 10, 1535. Thus, he is credited with bringing the Galápagos Islands to the world's attention. Because of Friar Tomás' letters, early maps of the coast of South America began to include the Galápagos Islands. The earliest of these is a vellum chart, thought to be from the 1530s. The islands then appear in Gerard Mercator's world map of 1569. Based on his letters, Friar Tomás did not enjoy his brief time on the Galápagos. The islands appeared inhospitable to humans, with the lack of water being critical. Other Spanish explorers visited, but most found the islands waterless, somewhat uninteresting, and very difficult to live in. They were seen as having little more to offer than giant tortoises as a food source. However, the strategic location of the islands (near the west coast of South America, but not too close) made them an ideal location as a haven for English pirates of the 17th century who sought to attack Spanish ships laden with precious metals. By the late 18th century the islands were being used as a land base for whaling operations in the Pacific, first by the British, then by the Americans. Colonists from Ecuador began settlements on Floreana in the 1830s, and the islands were annexed by Ecuador in 1832. The colony failed by 1852, as the colonists had used up the available resources by that time. Several additional attempts were made to colonize the islands by the Ecuadorans in the latter half of the 19th century.

Darwin and the Voyage of the *Beagle*

The most important biological investigations of the Galápagos Islands began almost by accident, when Charles Darwin (Fig. 2) landed there in 1835. In 1831, Darwin, then aged 22, convinced Captain Robert Fitzroy to let him join a charting voyage around South America on the *H. M. S. Beagle* (Fig. 3) as ship's naturalist. When setting off from England for a 5-year voyage, Darwin had little ambition for groundbreaking scientific research. On September 17, 1835 on the return route across the Pacific, the *Beagle* arrived at the Galápagos Islands, starting with San Cristóbal. Darwin went ashore there (September 17–22), then went on to visit Floreana (September 24–27), Isabela (September 29 to October 2) and finally spent time on Santiago (October 8–17). While the

Fig. 2 Charles Darwin, aged 40. Lithograph by T. H. Maguire, 1849. Courtesy of Wellcome Collection. CC BY.

Fig. 3 HMS Beagle. Oil painting by Fran Camós, used with permission.

rest of the crew of the *Beagle* updated Admiralty charts of the archipelago, Darwin collected geological and biological specimens on the islands.

At the time of his visit, Darwin had not yet developed the ideas he presented later. Upon his return to England, he began to realize the full significance of the differences among Galápagos species, particularly based on his observations of the different species of Galápagos mockingbirds on various islands, as well as the differences between the giant tortoises of the different islands. Having failed to label all of the localities where he had taken specimens in his own collections, Darwin went to his crewmates from the *Beagle*, asking to see the specimens that they had collected, to track down inter-island variations among birds, plants, and other species. Darwin was curious about how life had first come to these islands. Most of the species he observed on the Galápagos were endemic to the islands, yet they all showed relationships with species from the Americas. He reasoned that the ancestors of Galápagos species must have been accidental colonists from Central and South America that proceeded to diverge from their ancestral stocks after arriving in the Galápagos. His visits to multiple islands in the archipelago turned out to be critical to the development of his ideas, because he discovered evidence suggesting that evolution was proceeding independently on each island, producing at least some unique species. Darwin spent the next 24 years developing his ideas about natural selection before

publishing his book, 'On the Origin of Species'. He described this book as "one long argument" that stemmed from his five-week visit to the Galápagos Islands and attempted to include all life on earth. As the basis of evolutionary theory, this book changed the course of the life sciences, and linked Darwin inextricably with the Galápagos.

Galápagos Environments

The Galápagos Islands remain a living laboratory for evolutionary biologists. The islands are separated from the mainland of South America by almost 1000 km. So, as Darwin surmised, every species that lives on the Galápagos today is descended from a migrant species that arrived there from some other part of the world. Since the geologic history of the islands is well known, evolutionary biologists can measure the time available for a founding population of organisms to evolve daughter species on a given island or islands. For this reason, the Galápagos Islands are quite probably the most studied archipelago in the world. The Galápagos also have a unique set of environmental conditions that set them apart from other island groups. The archipelago straddles the Equator (Fig. 4) and the islands are surrounded by the cool Humboldt Current. The waters of this current are about 9 °C colder than a surrounding tropical water near the equator. The cold water holds more dissolved oxygen and upwelling of the current along the coast brings nutrients to the surface. This nutrient rich water supports abundant phytoplankton which are the basis of thriving marine ecosystem. The Cromwell is a warm current that flows along the Equator. It upwells at the Galápagos, carrying nutrient-rich waters to the surface. The convergence of these warm and cold currents at the Galápagos produces a unique mix of tropical and temperate environments; these are reflected in the unusual plants and animals that inhabit them, another unique biological feature of the Galápagos.

Fig. 4 Map of the Galápagos Islands.

Vegetation Zones

According to [Levin et al. \(2015\)](#), the flora of the Galápagos includes 1544 species of flowering plants including 241 endemic species. Most of the surfaces of these islands are covered by arid, semi-desert xerophytic (dry-adapted) vegetation. Only the upper elevations of the volcanoes are sufficiently high to receive more rainfall than the lowlands. Lush, tropical vegetation clothes these mountain tops. The island vegetation zones begin at sea level with a littoral zone, then upslope to the lowland arid zone, then further up into the mountain top humid zone of those islands with tall volcanoes.

The littoral zone is a narrow band of arid shoreline. The vegetation consists of salt-tolerant and xerophilous vegetation ([Fig. 5](#)). Stands of several mangrove species grow along calm lagoons. Common shrubs include Galápagos leatherleaf (*Maytenus octogona*)

Fig. 5 Plant species growing in the littoral and arid zones. and saltbush (*Cryptocarpus pyriformis*). Herbaceous plants that grow along the beach include shoreline purslane (*Sesuvium portulacastrum*), Galápagos carpet weed (*S. edmonstonei*), and beach morning glory (*Ipomoea pes-caprae*), which helps stabilize coastal dunes.

The arid zone, immediately inland from the littoral zone, is the most extensive ecoregion of the Galápagos. The arid zone ranges from 80 to 200 m in elevation. It covers some small islands entirely. Arid zone plant communities (Fig. 5) are the most diverse on the islands. As the name suggests, the arid zone is populated by drought tolerant, xerophytic plants, including cacti, trees, shrubs and herbaceous plants. The most well-known tree is the palo santo (*Bursera graveolens*). Other trees in this zone include the guayabillo (*Psidium galapageium*) and paga paga (*Pisonia floribunda*). Since cacti thrive in arid environments, quite a number of species grow in the arid zone, including the endemic genus *Jasminocereus* and the lava cactus (*Brachycereus nesioticus*). Other examples of endemic cacti include the prickly pear cacti *Opuntia echios* and *O. helleri*. The woody shrubs of the arid zone form the lower levels of the vegetative layers in this zone such as the endemic *Castela galapageia*, *Lecocarpus pinnatifidus* and other species of the genus *Lecocarpus*. Herbaceous plants have also adapted to this arid zone, including several endemic varieties of Galápagos tomatoes (*Lycopersicon cheesmanii*), passionflower (*Passiflora foetida*), and species of the endemic genera *Tiquilia* and *Chamaesyce*.

The humid zone (Fig. 6) lies above the arid zone on islands that have volcanic peaks above 300 m. There is also a transition zone between the arid and humid zones. This transition zone is an ecotone, supporting a mixture of plant species from both adjacent

Fig. 6 Plant species growing in the humid zone. *Pisonia floribunda* photo by Charles Darwin Foundation; *Miconia robinsoniana* photo by Bruce Marcot, US Forest Service; *Psidium galapageium* photo from Creative Commons; *Zanthoxylum fagara* photo by Wikipedia Creative Commons; *Scalesia* trees photo by Galápagos Conservation Trust.

zones. These include pega pega (*Pisonia floribunda*), Galápagos guava (*Psidium galapageium*) and Scalesia trees. Garúa fogs maintain this humid zone during the dry season. They form during the night and last well into the next day, depositing moisture that acts as a shield against plant desiccation in these high elevation areas. Garúa is a Spanish word meaning drizzle or mist. Along the Pacific coast of South America (Peru and Chile) and on the Galápagos Islands, Garúa is the moist cold fog that blankets the coasts, especially during the winter. Within the humid zone the following elevational layers of vegetation are found. They are lush and tropical as a result of increased moisture. From 300 to 500 m elevation, Scalesia trees are dominant, reaching 5–15 m in height. There are 20 different species of *Scalesia*, the plant kingdom's version of Darwin's finches. From 500 to 600 m elevation, wild lime (*Zanthoxylum fagara*) is most abundant. Shrubs replace trees above 600 m, as seen on Santa Cruz and San Cristóbal islands. Galápagos miconia (*Miconia robinsoniana*) is a shrub that grows 3–4 m tall at 600–700 m above sea level, where it is dominant. Sadly, this endemic shrub is nearly extinct because of the impacts of agriculture and livestock grazing (World Wildlife Fund, 2019).

Above 900 m, the vegetation has been described as a fern-sedge zone. In place of shrubs there are ferns, sedges, grasses, and Sphagnum mosses. The only tall plant on this mountain top zone is the Galápagos tree fern, *Cyathea weatherbyana*. A moisture loving plant, it grows where pools of water accumulate, such as collapsed lava tubes, potholes and other cracks and crevices.

Geologic Setting

As described by White and Burdick (2019), these oceanic islands are of volcanic origin and have been building for the past 4 to 5 million years. The Galápagos Islands are located on the Nazca tectonic plate. This tectonic plate is drifting eastward over the Galápagos hot spot. Hot spots are volcanic regions thought to be fed by underlying mantle that is anomalously hot compared with its surroundings. The volcanic history of the Galápagos hot spot can be traced by the two adjacent submarine ridges: the Cocos and Carnegie ridges. The Cocos ridge extends northeast from the Galápagos Islands and subducts beneath Costa Rica. The Carnegie ridge extends eastward from the islands and subducts beneath Ecuador. With the exception of the largest island, Isabela, each major island consists of a single large volcano. Isabela was formed from the combination of five volcanoes (Fig. 7).

Most of the islands have a distinctive conical shape associated with volcanic action. The mountainous islands have been formed through continuing eruption, building layer upon layer. Due to this volcanic formation, the islands are characterized by many steep slopes, with heights ranging from a few meters to more than 1600 m above sea level. Two distinct types of volcanoes occur in the Galápagos. In the west, on the islands of Isabela and Fernandina, large volcanoes with an “inverted soup-bowl” morphology and deep calderas occur. In the east, smaller shield volcanos formed with more gentle slopes (Galápagos Conservancy, 2019b). La Cumbre is an example of a shield volcano on Fernandina Island (Fig. 8).

The difference between these two types of volcanoes is apparently due to the difference in lithospheric thickness beneath them. The emergence of the Galápagos Islands from the Pacific is only the most recent series of events in the history of volcano building from the ocean floor, which may extend back 12–15 million years. Some of the islands are anchored more than 3000 m below the surface, on the Pacific Ocean floor. Earthquakes are common, as are other volcanic characteristics such as crater lakes and parasitic vents flanked by lava flows marking the summits. Other volcanic landscape features include fumaroles, lava tubes, sulfur fields and a variety of pumice, ash, and tuff ejected from the volcanoes.

Fig. 7 Satellite photo of the main Galápagos Islands, showing the location of volcanoes. Note the presence of five volcanoes on Isabela Island. Photo courtesy of NASA Jet Propulsion Laboratory.

Fig. 8 La Cumbre is a shield volcano on Fernandina Island in the Galápagos Islands. La Cumbre is also the youngest volcano in the Galápagos Islands. Photo courtesy of NASA.

Among the Galápagos Islands there are 21 emergent volcanoes of which 13 are considered active. Unlike the Hawaiian Islands, these volcanoes do not form a linear chain. However, the oldest volcanoes tend to be located in the southeastern area of the archipelago. The oldest islands in the Galápagos are South Plaza (just east of Santa Cruz Island) at 4.2 million years, and Española at 3.2 million years. These dates correspond to the time when these islands first rose above sea level. Determining the age of the islands is made possible through a method called potassium-argon dating, which can be used to estimate the age of volcanic rocks (basalts).

Historic eruptions have occurred on many of the Galápagos volcanoes, including Fernandina, Volcán Wolf, Alcedo, Sierra Negra, Cerro Azul, Santiago, Pinta, Floreana, and Marchena. Eruptions in the recent geologic past (the last 10,000 years) have also occurred on Volcan Darwin, Volcan Ecuador, Genovesa, San Cristobal, and Santa Cruz. A number of submarine volcanoes have also been active in this time. It is quite unusual for a mantle plume to produce so many simultaneous active volcanoes.

Island Biogeography and Biodiversity

How and when were the Galápagos Islands colonized by plants and animals? These islands are situated in the Pacific Ocean 900 km west of the coast of South America. Unraveling the biological history of these isolated islands presents a formidable challenge for biogeographers. Darwin's explanation for the biotic colonization of the islands focused on the ability of organisms to disperse over barriers from their centers of origin. He later speculated (Darwin, 1871: 363) that there might have been a land bridge connecting the islands to the South American continent. However, subsequent examinations of the regional marine geology, combined with the volcanic origins of the Galápagos, rendered such land bridge theories untenable.

Evolutionary biologists are fascinated by island ecosystems because of the clarity with which the species that inhabit them illustrate evolutionary processes. For this reason, as well as a world-changing historic visit by Charles Darwin, the Galápagos Islands are quite arguably the best-studied archipelago in the world.

As discussed by the Galápagos Conservancy (2019c), when considering the diversity of species that inhabit the Galápagos Islands, it is important to note the unbalanced nature of the flora and fauna, compared with continental species diversity. For instance, there are many native reptile species, but no amphibians; there is an abundance of land and sea bird species, but few native mammals. Plants with large flowers and big seeds are absent while grasses and ferns abound. It is likely that the ancestors of present-day Galápagos animals that had the ability to swim some distances, such as sea lions (*Zalophus wolfebaeki*), sea turtles (*Chelonia mydas*), and penguins (*Spheniscus mendiculus*) swam to the islands with the help of ocean currents. Non-swimming migrants, such as reptiles and small mammals such as rice rats (*Aegialomys galapagoensis*) were likely carried to the islands from the South or Central American mainland on rafts of plant debris. Most of these rafts would have sunk before reaching the Galápagos, but it would have only taken a handful of successful rafts washing ashore to explain the present reptile diversity in Galápagos. This "raft" theory of arrival also explains why there are no native amphibians, few mammals, and many reptiles in the Galápagos Islands—reptiles are the best adapted to deal with the harsh salty and sunny conditions of weeks at sea. Coastal plants, such as the mangroves and saltbushes of Galápagos, have seeds that are salt tolerant, and those seeds are also likely to have arrived by sea. Amphibians are too

prone to desiccation to survive weeks on the open ocean. Wind is thought to have played a major role in transporting spores of the ferns, mosses, and lichens to the Galápagos Islands. Vascular plants with heavier seeds are quite scarce in the Galápagos because those seeds would have had a more difficult time traveling by wind, except plants with plumed seeds designed for wind transport. This explains why members of the dandelion family (Compositae) are found throughout the Galápagos. Wind also likely transported small invertebrates to the islands, as well as a few species of weaker-flying land birds and two species of bats. Not surprisingly, only a tiny fraction of the South American bird fauna became established on the islands. However, sea birds are generally excellent fliers over long distances, so they simply flew to the islands. Birds likely brought with them hitch-hiking plant seeds or propagules that were attached to their feathers or feet, or even in their guts.

Migration Routes to the Galápagos

As described by Grehan (2001), three principal migration track patterns or routes connect the Galápagos with three sources of origin for the islands' biota: The Eastern Pacific, the Caribbean, and the Pacific basin. The Eastern Pacific track has been identified through species with distributions that connect the Galápagos with North and South America, bypassing Central America. The ancient migration routes of the ancestors of the species found today in both the Galápagos and Caribbean islands follow a track along the Caribbean/Cocos/Nazca plate boundary. Distributions shared between the Galápagos, America, and eastern Asia/Australasia represent a Pacific basin track. Clues concerning the origins of the Galápagos biota can be found by examination of sister species relationships between mainland and Galápagos taxa (Table 1).

East Pacific tracks

This group of Galápagos species are found today in either North or South America, but not in most of Central America. The dispersal mechanisms for this group of species include both passive (e.g. flightless weevils) and active (e.g. wasps) dispersal methods. The shortest migration route in this group connects the Galápagos Islands to Peru and Ecuador. In many cases, the migrant population of species that made it to the Galápagos has genetically diverged from the mainland population. When the island population evolves into a separate (although closely related) species, this is called *allopatric speciation*. This is a mode of speciation that occurs when populations of a species become isolated from each other to an extent that prevents gene flow between those two populations.

There are many examples of organisms that followed the East Pacific track migration route. The flightless weevil genus *Galapaganus* includes five Galápagos species and three species living in Ecuador and Peru. The wasp *Tachysphex galapagensis* has a sister species on the mainland, *T. peruanus* (Fig. 9). These wasps link the Galápagos with Peru. Likewise, the Galápagos snake *Alsophis biserialis* is linked with its sister species *A. elegans* in Peru and southern Ecuador. Further south a sister species relationship connects the Galápagos snake *Pilodrya hoodensis* with its Chilean relative *P. chamissonis*. The lizard genus *Microlophus* includes at least three Galápagos species and 14 mainland species, ranging between Ecuador and northern Chile. The single species of the plant group Solanaceae (nightshade family) that became established in the Galápagos is related to 82 species of the family found throughout Peru and Chile.

Table 1 List of Galápagos species with sister species elsewhere.

Taxon	Galápagos species	Relatives elsewhere
<i>Porifera</i>		
Sponge genus <i>Rhabderemia</i>	<i>R. destituta</i>	<i>R. mona</i> in Puerto Rico
<i>Insects</i>		
Weevil genus <i>Galapaganus</i>	10 flightless species	5 species in Peru and Ecuador
Wasp genus <i>Tachysphex</i>	<i>T. galapagensis</i>	<i>T. peruanus</i> in Peru
Rove beetle genus <i>Rothium</i>	2 species	4 species on Pacific coast of Mexico, Peru, Ecuador
Moth genus <i>Oxydia</i>	<i>O. lignata</i>	<i>O. hoguei</i> on Cocos Island
Shore fly genus <i>Paracanace</i>	2 species	6 species in Caribbean, Panama and Brazil
Flower beetle genus <i>Ablechrus</i>	<i>A. flavipes</i>	8 species in Cuba, Mexico, Guatemala, Panama, Venezuela
<i>Reptiles</i>		
Snake genus <i>Alsophis</i>	<i>A. biserialis</i>	<i>A. elegans</i> in Peru and Southern Ecuador
Snake genus <i>Antillophus</i>	2 species	<i>A. andreae</i> in Cuba; <i>A. parvifrons</i> in Hispaniola
Snake genus <i>Pilodrya</i>	<i>P. hoodensis</i>	<i>P. chamissonis</i> in Chile
Lizard genus <i>Microlophus</i>	At least 3 species	14 species from Ecuador to N. Chile
Lizard genus <i>Phyllodactylus</i>	8 species	7 species in Puerto Rico, Venezuela and Columbia
<i>Flowering plants</i>		
Plant genus <i>Lycium</i>	18 species	70–80 species in the Americas
Plant genus <i>Nolana</i>	<i>N. galapagensis</i>	17 species in Peru and Chile
Plant genus <i>Gossypium</i>	<i>G. klotzschianum</i>	<i>G. davidsoni</i> in Baja California, Mexico
Plant genus <i>Galvezia</i>	<i>G. leucantha</i>	8 species in S. California, Mexico, Ecuador, Peru

Sharp, Creative commons CC BY-SA 4.0.

Examples of species that followed the Caribbean track include the lizards in the genus *Phyllodactylus*. These lizards have close relatives in Columbia, Venezuela and Puerto Rico. Note how this track bypasses Central America. This Caribbean connection via North and South America also characterizes the distribution pattern of the plant genus *Lycium* where the Galápagos species, *L. minimum*, fills a geographic gap west of Central America that complements the Caribbean distribution to the east. This interrelationship between East Pacific and Caribbean distributions may also apply to the Galápagos finches (Fig. 10). Assuming the designation of *Tiaris obscura* as the nearest mainland relative is correct, then this bird group follows a Galápagos–South America track. The genera *Tiaris* and the Caribbean *Melanospiza* form the Galápagos finch sister group. This relationship extends the East Pacific track to include the Caribbean basin.

A northern track is represented by sister species of the cotton plants *Gossypium klotzschianum* and *G. davidsonii* linking the Galápagos with Baja California. A similar link occurs for the sister genus relationship of the foxglove genus *Gambelia* in California and Mexico and *Galvezia* in the Galápagos. The track for *Galvezia* comprises Galápagos, Ecuador and Peru.

Caribbean connections with the Galápagos which involve Central America are also quite common. The Galápagos species of *Oxydia* moths may be closely related to species of *Oxydia* on Cocos Island and to a species on the Caribbean island of Guadalupe.

Fig. 10 Eleven of the seventeen species of Darwin's Finches endemic to the Galápagos. Photos courtesy of the Charles Darwin Foundation.

A subgenus of the shore-fly genus *Paracanace* forms a track between Galápagos, Panama and Brazil, but not Cocos Island. The track of the soft-winged flower beetle *Ablechrus* also connects the Galápagos, Central America and the Caribbean.

Pacific tracks

Although many Galápagos organisms are most closely related to species on the American mainlands, there are also biogeographic relationships that link the Galápagos biota to the Pacific basin. For instance, the land snail genus *Tornatellides* is confined to the Pacific basin, and its presence on the Galápagos represents its easternmost locality. The shoreline spider genus *Desis* is found throughout much of the Indian and Pacific Ocean basins, with 13 species known from the ocean shores of East Africa, India, Australia, New Guinea, and Japan. The easternmost species is *D. galapagoensis* from the Galápagos. How did organisms cross from the western to the eastern Pacific? The tectonic history of the eastern Pacific provides the best available evidence of direct contact between the Galápagos hotspot and proposed former Pacific–Caribbean island arcs. Tectonic plate movements transported island arcs eastward, across the ancient Pacific basin. When these island arcs moved over the hotspot beneath the Galápagos, it would have been possible for island arc biota to disperse onto the volcanic landscape.

DNA Evidence

Genetic analysis is shedding new light on the biogeographic history of the Galápagos. A study by [Sequeira et al. \(2000\)](#) examined 15 species in the afore-mentioned weevil genus *Galapaganus* that are distributed on coastal Peru and Ecuador and include 10 flightless species endemic to the Galápagos islands. Genetic samples were obtained from seven species from the oldest Galápagos islands: San Cristóbal, Española, Floreana, and Santa Cruz. Based on genetic mutation evidence, the oldest species, *G. galapagoensis* on the oldest island, San Cristóbal, diverged from the remaining species in the Galápagos about 7.2 Ma. This estimate exceeds the geological ages of the extant emerged islands. However, this study is not a fluke, as dating of endemic Galápagos iguanas, geckos and lizards by genetic mutation rates produced very similar results. An apparent explanation for the disparity between geological and genetic timeframes is that about 7 Ma there were islands in the Galápagos region that subsequently sank under the surface of the ocean. These islands may have been the ones initially colonized by the ancestors of these organisms. This hypothesis has gained support from the recent geological research that identified 11-Myr-old sunken islands, south-east of the present location of the archipelago.

[Torres-Carvajal et al. \(2016\)](#) took a fresh look at the biogeography of the leaf-toed geckos (*Phyllodactylus*) endemic to the Galápagos Islands by analyzing DNA. Previous workers had proposed a scenario in which there were three separate colonization events for this group. The DNA study supported the three colonization scenario with an early colonization that included most species of *Phyllodactylus*, occurring 5.5 and 13.8 Ma, followed by a second independent colonization of *P. darwini* 3.03 Ma ago. A third colonization to Wolf Island by *P. gilberti*, occurred 690 ka. As with many other Galápagos organisms, the Pacific coast of South America seems to be the source for the founders of the Galápagos leaf-toed geckos.

Biogeographic Modeling

[Funk and Burns \(2018\)](#) studied the geographic origins of Darwin's finches through biogeographic modeling. Darwin's finches are considered a classic example of an adaptive radiation and have been the focus of numerous studies over the last 50 years. Few studies, however, have attempted to investigate the biogeographic origins of these birds. Biogeographic models run using eight regions suggest Darwin's finches arose from an ancestor in a long-distance dispersal event from the Caribbean Islands as opposed to the geographically closer mainland South America. However, models run using only five areas suggest equal probability between a Caribbean and a mainland South America origin to Darwin's finches. This study suggests equal probability for a Caribbean origin to Darwin's finches as a South American mainland origin. Overall, the Caribbean Islands appear especially important for the initial diversification of this group of birds, with many small-island restricted species diversifying early in the radiation. Colonization success was likely coupled with high dispersal ability and highly variable bill morphology to exploit vacant niche space ([Table 2](#)).

Origins of Galápagos Insects

According to [Peck \(2006\)](#), there are almost 2000 species of insects and 350 species of other terrestrial arthropods on the Galápagos Islands. Of the 376 native beetle species, there are 266 endemic species and 110 indigenous species with populations outside the Galápagos. Most beetle colonization was probably passive—either through the air as 'aerial plankton' or by sea-surface transport (rafting on oceanic flotsam) from Mexico, Central or South America. However, unlike plants and vertebrates, beetle colonization of the Galápagos has not led to much speciation. The average for the native beetle fauna is about 1.35 species per colonizing ancestor. Factors suppressing beetle speciation on the Galápagos include the lack of habitat diversity on the islands and the geological youth of the islands.

One example of beetle colonization on these islands is the rove beetle genus *Rothium*. A study by [Frank and Ahm \(2011\)](#) examined this group of beetles that are strictly marine coastal inhabitants. Their habitat includes the shore area that falls between the low and high tides. They are found on rocky headlands, specifically on rocks with algae, and in tidal pools. Four species of *Rothium* are found along the Pacific coasts of Mexico, Peru, Ecuador. Two species are found only in the Galápagos: *R. littoralis* and *R. ashlocki*. Presumably these evolved from an ancestor closely related to a mainland species from South America.

Vertebrate Fauna of the Islands

The islands are home to 8 native species of mammals, 27 species of reptiles, 45 species of birds, and 11 species of fish, making a total of 91 native species of vertebrates on and around the islands ([Table 3](#)). Of these 91 species, 11 are listed by the IUCN as 'Endangered,' 7 are 'Vulnerable,' and 4 are 'Critically endangered.' This means that one-quarter of the vertebrate species of the islands are seriously threatened. This short review focuses on just two groups of animals that are unique to the Galápagos Islands: the giant tortoises and the iguanas.

Giant tortoises

The native vertebrate fauna of the Galápagos is limited to reptiles, birds and mammals. Descriptions of these animals are provided by the [Galápagos Conservancy \(2019d\)](#). Probably the most famous of these animals is the giant tortoise (*Chelonoidis nigra* complex). Giant tortoises once lived on most of the continents of the world, but all were driven to extinction except the Galápagos tortoises and the giant tortoises of the Aldabra Atoll in the Indian Ocean. The Galápagos Islands were named for their giant tortoises; the old Spanish word *galapago* meant saddle, a term used to describe the shape of their shells. The closest living relative of the Galápagos giant

Table 2 Distribution, characteristics and diet of Darwin's Finches.

Species	Common name	Distribution	Physical characteristics	Diet
<i>Geospiza acutirostris</i>	Genovesa ground finch	Only on Genovesa	Small, sharply pointed beak	Arthropods in trees, small seeds
<i>G. conirostris</i>	Española cactus finch	Restricted to Española, Genovesa, Darwin and Wolf Islands (not where common cactus finch lives)	Resembles the small, fine-beaked common cactus finch	Main food source is prickly-pear cactus <i>Opuntia</i>
<i>G. difficilis</i>	Sharp-beaked ground finch	Fernandina, Santiago, Pinta, Genovesa, Darwin and Wolf Islands	Medium length, sharply pointed beak	Seeds, insects and flowers
<i>G. fortis</i>	Medium ground finch	All but the northern islands	Short, stout beak	Main food source is seeds
<i>G. fuliginosa</i>	Small ground finch	On most of the islands	Short, stout beak	Small seeds and skin parasites iguanas and giant tortoises
<i>G. magnirostris</i>	Large ground finch	Found on most islands, but absent from southeastern islands	Largest species of group; very stout beak	Uses beak to crack open nuts
<i>G. propinqua</i>	Genovesa cactus finch	Only on Genovesa	Thick, long and robust beak	<i>Opuntia</i> cactus pulp, flowers, fruits and insects
<i>G. scandens</i>	Common cactus finch	On the main islands	Large, crow-like beak	<i>Opuntia</i> cactus seeds, flowers, insects
<i>G. septentrionalis</i>	Vampire ground finch	Only on Wolf and Darwin Islands	Small, sharply pointed beak	Wet season: seeds, insects; dry season: takes blood of nesting seabirds
<i>Camarhynchus heliobates</i>	Mangrove finch	Fernandina and Isabela - now missing from Fernandina	Medium size beak	Arthropods and plant matter in mangroves
<i>C. pallidus</i>	Woodpecker finch	Isabela, Santa Cruz, San Cristobal, Fernandina, Santiago, and Penzón	Long stout beak	Picks insects from tree cracks and crevices, also eats seeds
<i>C. pauper</i>	Medium tree finch	Only on Floreana Island	Intermediate sized, stout beak	Arthropods
<i>C. parvulus</i>	Small tree finch	On all the main islands	Short conical beak	Arthropods
<i>C. psittacula</i>	Large tree finch	On all the main islands except Española, Genovesa	Largest of the tree-finches; with heavy, parrot like beak	Takes arthropods by pecking through tree bark
<i>Certhidea olivacea</i>	Green warbler-finch	Santiago, Rábida, Pinzón, Isabela, Fernandina, and Santa Cruz	Short, sharp beak	Catches insect on the wing
<i>C. fusca</i>	Gray warbler-finch	Darwin, Wolf, Española, Santa Fe, San Cristobal, Pinta, Floreana	Smallest of Darwin's finches; short sharp beak	Insects
<i>Platyspiza crassirostris</i>	Vegetarian finch	San Cristóbal, Santa Cruz, Floreana, Isabela, Marchena, Santiago, Pinta and Fernandina	Broad, stout beak	Plant buds, leaves, flowers and fruit

Data from Charles Darwin Foundation. (2019). Galapagos species checklist. <https://www.darwinfoundation.org/en/datazone/checklist?species=5093> and Cornell List of Neotropical Birds (2019) <https://neotropical.birds.cornell.edu/Species-Account/nb/home>.

tortoise is the South American Chaco tortoise, but this small tortoise is not thought to be the direct ancestor of the Galápagos tortoises. The first tortoises arrived on the Galápagos 2–3 million years ago, probably by drifting across from the South American coast on vegetation rafts or on their own. The fossil evidence shows that they were already large animals before arriving in Galápagos. They began by colonizing the eastern islands of Española and San Cristóbal, then they dispersed throughout the archipelago, eventually establishing at least 15 separate populations on 10 of the largest Islands.

There are two main morphological forms of Galápagos tortoises, the more primitive domed carapace and the saddle-backed carapace (Fig. 11). Domed tortoises tend to be much larger. They inhabit the larger islands that have humid highlands where forage is generally abundant and easily available. Saddle-backed tortoises evolved on the arid islands and are adapted to survive on little food and water during the frequent droughts. The front of their shell angles upward, allowing the tortoise to extend its head to reach taller plants, such as cactus pads.

One of the giant tortoise's most unusual adaptations, its ability to survive without food or water for up to a year, became the indirect cause of its demise. Pirates, whalers and fur sealers discovered that they could have fresh meat on board their ships by keeping live giant tortoises on board, hence massive exploitation of the species began. Within 200 years, between 100,000 and 200,000 tortoises had been taken by sailors for their meat. Three species have been extinct for some time, and a fourth species (*Chelonoidis abingdonii*) lost its last member, Lonesome George in 2012. It is estimated that 20,000–25,000 wild tortoises live on the islands today. They represent 11 living species. The conservation status of these 11 tortoise species are Vulnerable, Endangered, and Critically Endangered (Table 4) (Galápagos Conservancy, 2019e).

Table 3 Vertebrate animal species of the Galápagos Islands.

<i>Species</i>	<i>Common name</i>	<i>IUCN status</i>
Mammals		
<i>Arctocephalus galapagoensis</i>	Galápagos fur seal	Endangered
<i>Aegialomys galapagoensis</i>	Galápagos rice rat	Vulnerable
<i>Zalophus wolfebaeki</i>	Galápagos sea lion	Endangered
<i>Neorhynchus cinereus</i>	Hoary bat	Least concern
<i>Lasiurus borealis brachyotis</i>	Galápagos red bat	Least concern
<i>Tursiops truncatus</i>	Bottle Nosed Dolphin	Least concern
<i>Mesoplodon densirostris</i>	Blainville's beaked whale	Data deficient
<i>Ziphius cavirostris</i>	Cuvier's beaked whale	Least concern
Reptiles		
<i>Chelonoidis nigra</i> complex	Galápagos tortoise	Endangered
<i>Chelonia mydas</i>	Green sea turtle	Endangered
<i>Amblyrhynchus cristatus</i>	Marine iguana	Vulnerable
<i>Conolophus subcristatus</i>	Galápagos land iguana	Vulnerable
<i>Microlophus albemarlensis</i>	Galápagos lava lizard	Least concern
<i>M. bivittatus</i>	San Cristóbal lava lizard	Near threatened
<i>M. delanonis</i>	Española lava lizard	Data deficient
<i>M. duncanensis</i>	Pinzón lava lizard	Not threatened
<i>M. grayii</i>	Floreana lava lizard	Not threatened
<i>M. habelii</i>	Marchena lava lizard	Least concern
<i>M. indefatigabilis</i>	Santa Cruz lava lizard	Least concern
<i>M. pacificus</i>	Common Pacific iguana	Least concern
<i>Pseudalsophis biserialis</i>	Eastern Galápagos racer	Near threatened
<i>P. darwini</i>	Darwin's racer	Least concern
<i>P. dorsalis</i>	Central Galápagos racer	Near threatened

Galápagos iguanas

Galápagos iguanas are thought to have a common ancestor that arrived on the islands from the South American continent, floating on rafts of vegetation. Land and marine iguanas diverged about 10.5 million years ago. Genetic evidence suggests that the pink iguana (*Conolophus marthae*), diverged from the other land iguanas approximately 5.7 million years ago, before the current islands existed. The divergence between the two yellowish iguanas is fairly recent.

There are three species of land iguana found in the Galápagos Islands. The well-known yellowish land iguanas include *Conolophus subcristatus* (Fig. 11), native to six islands, and *Conolophus pallidus*, found only on the island of Santa Fe. A third species of land iguana (*Conolophus marthae*), the pink iguana, is found only on Wolf Volcano at the northern end of Isabela Island. It has a pinkish head, and pinkish and black body and legs, often with black stripes. This recently discovered species is morphologically, behaviorally, and genetically distinguished from the other two.

Land iguanas are more than 1 m long and may weigh up to 13 kg (30 lbs). They live in the arid zone of the Islands, and as ectotherms (animals whose regulation of body temperature depends on external sources, such as sunlight or a heated rock surface) they must warm their bodies in the mornings before they can fully function. They must avoid overheating from midday sun by resting in the shade of cacti, rocks, trees or other vegetation. At night they sleep in underground burrows to conserve their body heat. They eat low-growing plants and shrubs, fallen fruit and cactus pads. The moisture from these plants provides the iguanas the moisture they need to survive long droughts.

Land iguanas can live for more than 50 years. A census taken in 1959 found healthy, stable land iguana populations. In 1975, populations on two different islands were almost destroyed in <6 months by feral dog packs. Unlike tortoises, adult iguanas are not predator-proof. Saving them meant removing them from their natural habitat until dogs were eliminated. A breeding and rearing center was quickly established, but it was not large enough for all the adults. So, 38 Santa Cruz iguanas were released on the small islets of Venecia off the northwest coast of Santa Cruz. This population thrived, and the breeding program continues today. Many of the offspring have been repatriated to Santa Cruz and southern Isabela following the removal of feral dogs from the islands. The land iguana breeding and rearing program has been considered a complete success.

The marine iguana (*Amblyrhynchus cristatus*, Fig. 11) is the only sea-going lizard in the world. This extraordinary animal lives on land but feeds on seaweed. It finds its food on exposed rocks, in subtidal areas, and in shallow ocean waters. The iguanas dive as deep as 30 m and may spend up to 1 hour underwater. When diving 7 m or deeper, they often remain submerged for 15–30 min. However, these lizards are also ectotherms, so they cannot expose themselves to cold sea water for longer periods. They must climb out onto the shore to warm up. These iguanas have a short, blunt nose, adapted to feeding on algae growing on rocks. Unlike other lizards, their flattened tail propels the iguanas through the water while their legs hang at their sides. Iguanas have a gland to help them rid themselves of excess salt, consumed along with the algae. This gland is connected to their nostrils.

Marine iguanas are found throughout the islands in concentrations of up to 2700 individuals per km in some areas. The total population is estimated between 200,000 and 300,000. Changes in ocean currents associated with El Niño events cause the greatest

mortality in marine iguanas, with up to 70% dying in some populations in the great 1982–83 El Niño. El Niño causes changes in water temperatures that directly affect marine life around the islands. Upwelling from the Equatorial Undercurrent is reduced during El Niño events. This reduces the food supply in the near-surface waters.

Conservation Issues

All remote islands are biologically fragile. The few species that manage to become established on such islands give rise to many endemic species that fill the empty ecological niches. Over millions of years, healthy, functional island ecosystems are formed. Then, sooner or later, people arrive. People invariably damage the natural ecosystems of the lands they enter, but human impacts on

remote islands are far more devastating. The indigenous fauna is exposed to the depredations of predators they have never seen before. Endemic species are particularly vulnerable to extinction because once the native populations are gone, there is no other source of these organisms to re-colonize the island.

It is instructive to compare the history of human colonization of the Hawaiian Islands with that of the Galápagos. In the Hawaiian Islands, the eggs of ground-nesting birds were eaten by rats that arrived with the Polynesians, and many species were driven to extinction. On the Galápagos Islands, the giant tortoises fell prey to sailors who killed them in their thousands and drove many species to extinction. In Hawaii the lowland ecosystems were essentially destroyed as the native vegetation was replaced by agricultural crops, while the highlands were left virtually undisturbed. Ignoring the arid lowlands of the Galápagos, the colonists cut down forests on the highland regions of Floreana to create pastures and plant crops, including citrus. The lowlands of the Galápagos Islands are simply too arid to support agriculture, as demonstrated by multiple failed attempts by Ecuadoran immigrants to introduce farming to the islands in the 19th century. The early 19th century colonists unwittingly wrought more havoc with island ecosystems by the importation of goats, pigs, cattle and donkeys to the islands. The Polynesian colonists imported only three domesticated animals to the Hawaiian Islands: dogs, chickens and pigs. As previously mentioned, they also accidentally introduced rats to the islands.

As discussed by The Galápagos Conservancy (2019a), human impacts have resulted in substantial ecosystem damage on the islands. These impacts include major reductions in populations of fur seals, giant tortoises, groupers, lobsters, sea cucumbers, and whales. Human modifications of ecosystems have been greatest on the colonized islands of Floreana, Santa Cruz, San Cristobal, Baltra, and Isabela. The other easily accessible islands have also suffered ecological damage. These include Santiago, Española, Pinta and Pinzón. Some of the most important ecological disturbance on the Galápagos has come from the introduction of more than 1400 species of plants and animals.

History of protection of the islands

Government actions to preserve Galápagos ecosystems began in 1934, when the government of Ecuador adopted a decree to protect key species, regulate collections, and control visiting yachts. A 1936 the US government backed this law by mandating confiscation of all Galápagos animals taken in violation of the Ecuadorian law. That same year, the Ecuadorian government declared the Galápagos Islands a national reserve and established a national Scientific Commission to design strategies for the conservation of the islands. In 1959 the Ecuadorian government passed a law making all the Galápagos Islands a national park, except for those areas owned by existing colonists. The new law also banned the capture of species, such as iguanas and tortoises, and made port captains responsible for implementing the new rules. Then in 1969, another Ecuadoran legislation defined the borders of the National Park and gave legal status to the National Park Service as a conservation organization.

Marine biosecurity

Campbell et al. (2015) discussed a series of actions to protect the native marine biota of the Galápagos. Their recommendations stem from the results of two workshops on the topic of marine biosecurity in the Galápagos Islands (GI). These recommendations include the following:

- (1) Establish a baseline of known marine introduced species currently in the GI. Baseline studies enable prevention of new species and allow conservation authorities to make reliable response decisions when new organisms are found.
- (2) Encourage dive and tourism operators to help watch for non-native species. Outreach and education materials should highlight risks and harmful behaviors. Previous community surveillance has helped reef monitoring programs to provide early warning for pests such as the Crown of Thorns starfish.
- (3) Conduct baseline evaluations of Ecuadoran seaports, to interdict exotic species before they leave port and sail to the GI.

- (4) Establish a regulatory framework to prevent invasive species entering the Galápagos Islands in ship's ballast water. All vessels carrying ballast water into the Galápagos Islands should either undertake ballast water exchange at sea in compliance with the IMO Guidelines, or not discharge while in the Galápagos Islands.
- (5) Require vessels to have their hulls properly maintained, to prevent invasive species entering Galápagos Islands waters on ship's hulls.
- (6) Stop allowing international cruise vessels entering Galápagos waters. This has been accomplished by cruise ship passengers transferring to smaller tourist boats (16–100 passengers) outside of Galápagos Islands marine park waters. These smaller boats are based in the Galápagos Islands and are used for tourist island-hopping trips.

Galápagos Islands tourism began in earnest within the last few decades. The number of available tourist sites has increased from 35 land-based sites in 1983 to 169 marine sites in 2014. This has greatly increased the connectivity between islands. Most tourists today visit the Galápagos Islands ports of Santa Cruz and San Cristobal on their way to multi-day excursions on live-aboard cruise vessels. Tourists now fly in and then join cruises or stay on land. Island based tourism is also expanding with many inter-island day trips now available for land-based tourists. There is now so much tourism in the Galápagos Islands that the visitors are in danger of loving the islands to death. According to statistics from Galápagos National Park, the number of visitors to the islands increased by 39% between 2007 and 2016, from 161,000 to 225,000. The land-based portion of those tourists jumped 92% from 79,000 to 152,000. One reason for this rapid growth has been the increasing availability of hotels on the islands. In 2006 there were 65 hotels on the islands. In 2017, that number increased to 317. In 2018, a group of 35 tour operators group sent a letter to Ecuador's tourism minister to express their concern about the rising impacts of land-based tourism in the Galápagos Islands. The onslaught of tourists has the potential to harm its much-photographed landscapes and beaches as well as wildlife such as giant tortoises, sea lions and iguanas (Fig. 12). The letter asked the minister to limit and more carefully regulate land tourism.

Conclusions

The Galápagos Islands are a living laboratory for evolutionary biologists, biogeographers and ecologists. As with all isolated island groups, the native biota are descendants of a handful of species that flew, swam, or drifted on debris rafts onto the shores of the islands, thousands or even millions of years ago. Many of these founding organisms radiated into groups of endemic species, thereby increasing the biodiversity of the islands. But the Galápagos biota are an odd mixture of plants and animals. There are many native reptile species, but no amphibians; there is an abundance of bird species, but few native mammals. Plants with large flowers and big seeds are absent while grasses and ferns abound. The peculiarities of the Galápagos wildlife intrigued the young Charles Darwin, starting him on an intellectual journey that eventually produced his theory of survival of the fittest and evolution. The colonization of the islands by humans brought ecological disturbances of ever-increasing intensity until the Ecuadoran government began to take steps to ensure conservation of the islands' unique biota. The focus of much of the current conservation efforts is the prevention of the entry and spread of invasive species, both on land and in the sea.

Abstract

Wallacea is remarkable for a high degree of endemism. This region consists of three distinct island groups, namely Sulawesi, Lesser Sunda, and Moluccas. As the biggest island in this region, Sulawesi has several distinct forest types that provide habitat for the high number of endemic mammals and birds. Lesser Sunda Islands also has a unique biodiversity; most of its islands were very young geologically and have never been connected to a landmass. Therefore, their flora and fauna evolved independently. Similarly, the Moluccas region has high avian biodiversity, that is, provides home for 579 avifauna species, in which 83 species are endemic to the region. The other island described in this article is Krakatoa Island which is located between the islands of Sumatra and Java in the Republic of Indonesia. Its eruption in 1883 was one of the most violent volcanic events of modern history. This eruption has provided opportunities for long term ecological research on tropical island biogeography and succession. Krakatoa has also been an excellent site for biogeography studies.

Wallacea

Introduction

Alfred Russel Wallace, an explorer and naturalist, was born in 1823 in Usk, Monmouthshire. Summarized from his book *The Malay Archipelago*, he provided a view that the Indonesian Archipelago was inhabited by two distinct faunas, one in the east and one in the west. Based on the distribution of birds, he placed the boundary between Lombok and Bali and between Borneo and Sulawesi. The line that Wallace drew came to be known as Wallace's Line (Fig. 1). This line separates the Asian dominated avifauna of the Greater Sundas (Borneo, Sumatra, Java and Bali) from the Australasian-dominated avifauna of Papua and Wallacea (Sulawesi, Lesser Sunda, and Moluccas).

Wallacea region is known as a distinct island group in Eastern Indonesia (Fig. 1) including Sulawesi (A), Lesser Sunda (B), and Moluccas islands (C). Sulawesi is the largest island within this region, while the Lesser Sunda (Nusa Tenggara) and the Moluccas (Maluku) consist of many small to medium-sized islands. As reported by Burung Indonesia (2014), the largest island, Sulawesi, contributes the largest forest cover (56%) of Wallacea's forest, while the Moluccas and Lesser Sunda have only 24% and 19%, respectively. Evergreen and semi-evergreen forests dominates in Sulawesi and the Moluccas. According to Whitten et al. (1987), forests in Wallacea region is represented by some species of dipterocarps, including *Anisoptera* spp., *Hopea* spp., *Shorea assamica*, and *Vatica* spp. Distinctive ebonies (*Diospyros* spp.) were common in dense clumps in the lowland forests. Meanwhile, Monsoon forest (typically dominated by *Pterocarpus indicus*, also contain the remaining stands of Sandalwood *Santalum album*) dominates in Lesser Sundas.

According to the Köppen-Geiger climate classification, the predominant climate in Sulawesi can be described as the tropical rainforest climate (Af) (En.climate-data, 2018). Besides that, the Sulawesi region has several other different climates. The Central and Southeast region of Sulawesi share similar climate types, namely the oceanic climate (Cfb), the tropical monsoon climate (Am), and the tropical savanna climate (Aw). West Sulawesi has also the oceanic climate (Cfb) and tropical monsoon climate (Am). The Gorontalo region experiences the tropical monsoon climate (Am). Among those regions, North Sulawesi has only the tropical rainforest climate (Af). There is significant rainfall throughout the year in North Sulawesi, even though during the driest month.

Fig. 1 Wallace's line and group of islands within Wallace region.

The climates of the Lesser Sunda Islands (Nusa Tenggara) are dominated by the tropical savanna climate (Aw) and the tropical monsoon climate (Am). Only a few regions experience the oceanic (Cfb) and the tropical rainforest climate (Af). The Subtropical highland oceanic climate (Cwb) covers only a small region in East Nusa Tenggara. In Moluccas (Maluku), the tropical rain forest climate (Af) predominantly covers the region, followed by the tropical savanna climate (Aw), the tropical monsoon climate (Am) and the oceanic climate (Cfb). Whereas the North Moluccas region only experience two climates, which are the tropical savanna climate (Aw) and the tropical monsoon climate (Am).

Biodiversity

Biodiversity in Wallacea region is very unique, and contains many endemic species. The drivers of speciation within this region include isolation, periodic connection to the Australian and New Guinean land masses, and the complex patterns of tectonic movement and volcanic activity, splitting and re-forming islands (Burung Indonesia, 2014). Table 1 below presents the summary of biodiversity of Wallacea. Examples of Wallacea's fauna are shown in Figs. 2 and 3. The brief review of each main island groups then is described in the following section.

Sulawesi Island

The Wallacea region is home to many endemic species. Sulawesi has the highest endemism because of its long isolation from Asia and Australia, and it has several distinct forest types that provide habitat for a high number of endemic mammals and birds (Whitten et al., 1987). Summarized from Simay et al. (2009), Burung Indonesia (2014) and IUCN (2018), Sulawesi is home to at least 103 endemic species (Table 2), comprised of 4 species from the plant kingdom and 99 species from the animal kingdom. Those from the animal kingdom are four species of butterflies, three species of crustaceans, three species of fishes, four species of amphibians, three species of reptiles, 27 species of birds, and 55 species of mammals. Whereas the endemic plant species are three species of Magnoliopsida and one species of Liliopsida.

Lesser Sunda Islands

The Lesser Sunda Islands (Indonesian: Kepulauan Nusa Tenggara) consist of a group of islands situated north of the Australian continent. The main Lesser Sunda Islands, from west to east, are Lombok, Sumbawa, Sumba, Flores, Alor Archipelago, Wetar, and Timor. Most of those islands belong to the territory of the Republic of Indonesia, except for the eastern part of Timor Island which belongs to the state of Timor Leste.

Most islands of the Lesser Sunda Islands group are very young geologically (1–15 million years old) and have never been connected to a landmass, which means that their flora and fauna evolved independently (De Lang, 2011). It is widely known that the largest lizard in the world, the Komodo Dragon *Varanus komodoensis*, is endemic to this region (Fig. 4). Specifically, the Komodo Dragon inhabits the Komodo Island, Rinca, Gili Motang, Gili Dasami, and Flores (Ciofi et al., 2007). One of the world's rarest turtle namely the Rote Snake-necked Turtle *Chelodina mccordi* is also endemic in this region (specifically in Rote Island), and this species was listed in Appendix II CITES in 2004 (Endarwin et al., 2005).

Table 1 Summary of biodiversity lives in Wallacea region

<i>Taxa</i>	<i>Number of species</i>	<i>Number of endemic species</i>	<i>Examples of the endemic species</i>
Mammals	222 (terrestrial)	127 (57%)	Babirusa <i>Babirusa</i> sp. Anoa <i>Bubalus depressicornis</i> , <i>B. quarlesi</i> . Tarsiers <i>Tarsius</i> sp. Timor Deer <i>Rusa timorensis</i> (Fig. 2)

Insects (Lepidoptera and Odonata)	–	40	Murphy's Crow <i>Euploea caespes</i> Wallace's Golden Birdwing <i>Ornithoptera Croesus</i> <i>Protosticta rozendalorum</i> <i>Procordulia lompopatang</i>
Freshwater mollusks	NA	NA	<i>Tylomelania kruiemeli</i> <i>Miratesta celebensis</i>

Summarized from Simay et al. (2009), Burung Indonesia (2014) and IUCN (2018).

De Lang (2011) revealed that 29 terrestrial and semi-aquatic snake species were known to inhabit the Lesser Sunda Islands (Nusa Tenggara). Of these, eight were endemic to the area: *Boiga hoeseli*, *Coelognathus subradiatus*, *Dendrelaphis inornatus*, *Stegonotus florensis*, *Cylindrophis opisthorhodus*, *Broghammerus timoriensis*, *Liasis mackloti* and *Typhlops schmutzi*. Insular endemism was only found at the subspecific level, including *Liasis mackloti dunni* (Wetar Island), *Liasis mackloti savuensis* (Sawu Island), *Ramphotyphlops polygrammicus brongersmai* (Sumba Island), *Ramphotyphlops polygrammicus elberti* (Lombok Island) and *Ramphotyphlops polygrammicus florensis* (Flores Island).

The Lesser Sunda Islands also contains high avian biodiversity. For example, 266 avifauna species were found on Lombok Island, 267 in Sumbawa, 292 in Sumba, 335 in Flores, 242 in Komodo, and 323 in West Timor (Avibase Data, 2018). In late 2017, one new avifauna species from family Meliphagidae was found in Lesser Sunda Islands, namely *Myzomela irianawidodoae*. This species is endemic to Rote Island, and was named after the current First Lady of Indonesia Mrs. Iriana Widodo. Another endemic species in this region is the Rinjani Scops Owl *Otus jolandae* (Fig. 5), which was first described by Sangster et al. (2013).

Molucca Islands

The Molucca Islands (Indonesian: Kepulauan Maluku) is situated in the Banda Sea. The major islands are Halmahera, Buru, Ambon, Seram, Ternate, Tidore, and Aru. This region has attracted the interests of many scientists across the past centuries, that is, Georg Eberhard Rumphius (Botanist, *Herbarium Amboinense* published in 1741), Alfred Russel Wallace (Naturalist, *The Malay Archipelago* published in 1890). This region is known from the past as the *Spice Islands of Indonesia*, since it was the world's original source of nutmeg *Myristica fragrans* and clove *Syzygium aromaticum*; a title that contributed to the start of European Colonialism in the region. Sago Palm *Metroxylon sagu* can also be found in several locations in Molucca since it is the source of the staple food for the local community (Sasaoka et al., 2014). Recent data revealed that Molucca has about 97 vascular plants in 53 genera and 34 families, with *Ecua moluccensis* as one of the endemic vascular plant species (Terrestrial-Biozones, 2018).

The Moluccas region has high avian biodiversity. From the Avibase data record (2018), it is known that the Moluccas region provides home for 579 avifauna species, of which 83 avifauna species are endemic to the region. The largest island in this region, Halmahera, play an important role in providing habitat for 25 of 27 of the endemic bird species in North Molucca (Burung Indonesia, 2018). One example is at the Aketajawe-Lolobata National Park, where 55 bird species from 25 families inhabit this conservation area (Arini and Kinho, 2014). Seventeen of these species were identified as endemic to Maluku and Halmahera Islands, namely the Rufous-bellied Triller *Lalage aurea*, Cinnamon-bellied Imperial Pigeon *Ducula basilica*, Scarlet-breasted Fruit Dove *Ptilinopus bernsteinii*, Grey-headed Fruit Dove *P. hyogaster*, Blue-capped Fruit Dove *P. monacha*, Azure Dollarbird *Eurystomus azureus*, Long-billed Crow *Corvus validus*, Paradise-crow *Lycocorax pyrrhopterus*, Wallace's Standardwing *Semioptera wallacei*,

Fig. 3 Maleo birds *Macrocephalon maleo* and their underground nest at the Bogani Nani Wartabone National Park, Sulawesi. Photo by I.P. Yuda (2018).

White-streaked Friarbird *Melitograis gilolensis*, Dusky Friarbird *Philemon fuscicapillus*, Ivory-breasted Pitta *pitta maxima*, Chattering Lory *Lorius garrulus*, White Cockatoo *Cacatua alba*, Moluccan Hanging Parrot *Loriculus amabilis*, Seram Golden Bulbul *Ixos affinis*, Cream-throated White-eye *Zosterops atriceps*. Among those, the White Cockatoo and the Wallace's Standardwing are listed in IUCN Red List,

as well as in Appendix II CITES (IUCN, 2018). Due to its notable endemism, Halmahera and its adjacent islands (i.e., Morotai, Bacan, Obi, etc.) are recognized as the World's 10th Endemic Bird Area (EBA) by BirdLife International; it is well known as the Northern Maluku Endemic Bird Area (Stattersfield et al., 1998).

Threats to Wallace Biodiversity and Conservation Efforts

It has been described above that Wallacea region provides home for numerous endemic species. However, some concerns need to be addressed in order to preserve the unique biodiversity of the region. There are several threats to biodiversity in Wallace region (Irham, 2012; Arini and Kinho, 2014; Gillespie et al., 2015; Riyanto et al., 2017; IUCN, 2018). Some terrestrial animals were hunted or trapped for food (i.e., Sulawesi Giant Squirrel, Sulawesi Fruit Bat) or as treatment for ailments (i.e., Sulawesi Hornbill) or traded as pets (i.e., White Cockatoo, Wallace's Standardwing). Similarly, aquatic animals were also fished and harvested as food sources (i.e., Harlequin Shrimp Sulawesi, Sulawesi Forest Turtle). Furthermore, logging/wood harvest or deforestation cause major threats to biodiversity in the Wallace region (i.e., to both Herpetofauna and Avifauna). Human activities, such as residential and commercial development, energy production, mining activity, or the modification of natural systems, such as water resource management, also threaten biodiversity in the region (i.e., Harlequin Shrimp in Sulawesi). Other threats to the endemic species include the invasion of non-native alien species and diseases (i.e., Nile perch towards Caridina Shrimp). Considering these problems, conservation efforts/program are urgently implemented within this region. Since resources are limited for this region, conservation programs often compete with other priorities that provide more economic benefits for people in the Wallacea region (Burung Indonesia, 2014).

One approach conducted by the Indonesian Government was to ratify key international ecological conventions. For example, the Indonesian Government ratified the Ramsar Convention (Convention on Wetlands of International Importance especially in Waterfowl) in 1991, which resulted in the establishment of seven Ramsar sites in Indonesia, including Aopa Watumohai Peat Swamp National Park in South East Sulawesi region. The Indonesian government also ratified the United Nations' Convention on Biological Diversity by issuing the Indonesia Constitution Number 5 year 1994 (link: <https://pih.kemlu.go.id/files/UUU-594.pdf>), also ratified the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES) by issuing the Presidential Decree Number 43 year 1978 (link: <https://surajis.files.wordpress.com/2015/06/keppres-no-43-tahun-1978-tentang-ratifikasi-cites.pdf>).

The establishment of conservation areas in Indonesia, including within the Wallacea region, reflects the strong commitment of the Indonesian government to preserve their valuable biodiversity. Indonesia has established 521 conservation areas, including 221 nature reserves, 75 wildlife reserves, 50 national parks, 115 nature recreational parks, 13 game hunting reserves, and 23 grand forest parks (FORCLIME, 2017). Among those, Sulawesi Island has 21 nature reserves, 17 wildlife reserves, and 8 national parks. The Lesser Sunda Islands region contains 13 nature reserves, 5 wildlife reserves, and 6 national parks (one example is presented in Fig. 6), and the Moluccas Islands contain 18 nature reserves, 5 wildlife reserves, and 2 national parks.

Krakatoa

Introduction

The island of Krakatoa (or Indonesian: Krakatau) is in the Sunda Strait between the islands of Sumatra and Java and is part of the Republic of Indonesia. This recent volcano group consists of four islands, namely Rakata, Sertung, Panjang, and Anak Krakatau. The first three islands are the remaining formation of Mt. Krakatau's ancient caldera. Meanwhile, Rakata Island is a volcano that grew together with the Danan and the Perbuatan (Self and Rampino, 1981; Winchester, 2003). Its eruptions in 1883 were some of the most violent volcanic events of modern history. The sounds of the explosions were heard in Sri Lanka (formerly Ceylon, in southern

Fig. 6 Kelimutu National Park. Photo by L.P.E.K. Yuni (2016).

India), Myanmar (formerly Burma), Manila (the Philippines), Doreh in Geelving Bay (New Guinea), and in Perth (Australia). It was estimated that the sound was transmitted over one-fifteenth of the surface of the earth, at a radius of about 3333 km—if a circle is drawn from Krakatau (Verbeek, 1884). The explosion was followed by a massive tsunami of which the most destructive wave was estimated at about 30–41 m in height (Metzger, 1884). Villages and towns near Krakatau, in both Sumatra and Java, were destroyed or seriously damaged; 36,417 (Metzger reported 32,635 killed by the eruption through November 1883 (2)) people were killed and thousands were injured (Winchester, 2003). The Volcanic Explosivity Index (VIE) of the 1883 eruption was 6, and rock materials were ejected across approximately 25 km³. Two-thirds of the island of Krakatau was destroyed.

Post 1883 Eruption: Current Activity

The 1883 eruption nearly wiped out two-thirds of Krakatau. Since 1927, a number of submarine eruptions have formed a new island in the original location. The island known as *Gunung Anak Krakatau* ("The Child of Krakatau") appeared in 1929, and has continued to grow at an average growth rate of approximately about four meters of height per year.

In 2000, the volume of the mountain body was estimated 5.52 km³. If Anak Krakatau's growth in height and volume remain consistent, then its volume in 2020 will be bigger than the volume of Rakata, Danan and Perburuan prior to the 1883 eruption (Sutawijaya, 2006). Since 1927, 45 series of eruptions have been confirmed, lasting between 3 and 12 months, and the VIEs varied from 1 to 3 (Global Volcanism Program, 2013). The eruption in 1952 destroyed the vegetation of Anak Krakatau Island (Thornton et al., 1988).

Anak Krakatau has continuously erupted since June 2018, with a massive eruption (Fig. 7) recorded in December 2018 (PVMBC, 2018b). On 22 December 2018, the eruption caused tsunami waves that wiped out the coastal areas of Banten (West Java) and Lampung (Southern Sumatra). At least 426 peoples were reported killed and thousands were injured due to the tsunami (BNPB, 2018). Due to these eruptions, the height of Anak Krakatau decreased to about 110 m asl (formerly was 338 m asl) since it lost about 150–180 million m³ of its volume (PVMBC, 2018a).

Biological Studies

Krakatau has attracted the interest of many biologists since the 1883 eruption. This eruption provided opportunities to research long term ecological succession in the tropics and explore the facets of island biogeography. For example, after the biota of Krakatau was totally destroyed, floral recolonization has been studied since 1886; this was initiated by Professor Treub of Buitenzorg, who visited the island 3 years after the eruption (Hill, 1937). Meanwhile the study of the faunal recolonization started in approximately 1908 (Thornton et al., 1988). Further intensive studies on the recolonization process from 1919 through 1933 were conducted by (Dammerman, 1922, 1948) and (Docters van Leeuwen, 1936).

There were no field surveys in the islands during the Asia-Pacific War (Yamane, 2013). In 1979, a two phase program called the Krakatoa Centenary Expedition was launched by British scientists to comprehensively survey the area just 100 years after the

Fig. 7 An aerial view of Anak Krakatau volcano during an eruption on 23 December 2010. Scientists say that the volcano is now only about one-quarter of its size after its eruption and collapse (Nurul Hidayat/ Bisnis Indonesia).

catastrophic 1883 eruption (Thornton and Rosengren, 1988). Animal field surveys resumed by Japanese and Australian team in the 1980s (Yamane, 2013).

Various study topics have been carried out in the islands, included recolonization (Thornton et al., 1988; Whittaker et al., 1989; New, 2015), development of flora and vegetation succession (Hill, 1937; Whittaker et al., 1989; Partomihardjo et al., 2004), forest dynamics (Whittaker et al., 1989), plant-animal interactions (Whittaker and Jones, 1994; Whittaker and Turner, 1994), the relevance of island biogeography theories (Thornton et al., 1988, 1990, 2002; Bush and Whittaker, 1993; Yukawa et al., 2000; Zabka and Netwig, 2002), and the consequences of colonization on genetic diversity (Barber et al., 2002; Parrish, 2002; Zavodna et al., 2005).

Biogeography and Biodiversity

The Krakatau Islands have been an excellent site for biogeography studies for the following reasons: (1) well known starting points of re-colonization, (2) very little human influence during the period of re-colonization, (3) well defined sources of colonization from Sumatra and Java, and (4) a well-documented biological history (Zabka and Netwig, 2002). MacArthur and Wilson (1967) tested their equilibrium model of immigration and extinction processes using their rate of recolonization by bird and vascular plants in the Krakatau Islands. They used bird data through 1933 and concluded that the resident terrestrial bird species on Rakata and Sertung had approached equilibrium, while the vascular plant species were still increasing. More recent studies using additional data on vertebrates collected from 1889 through 1986 revealed that vertebrate colonization and species turn-over in the islands has continued (Thornton et al., 1988). This study also reported that the actual number of vertebrate species was 9 terrestrial reptiles, 36 resident terrestrial birds and 15 species of bats. Among of them were recent colonizers: Malay False Vampire Bat *Megaderma spasma*, the insectivorous Whiskered Bat *Myotis muricola*, the Large Fruit Bat *Pteropus vampyrus*, and the Tokay *Gekko gecko* and King Gekko *monarchus*.

Zabka and Netwig (2002) found 44 Salticid (spider) species in the islands. However, they revealed that there was no correlation between area and species diversity. Even though the smallest island, Anak Krakatau had the richest species diversity of spider (28 species), compare to Rakata (22 species), Panjang (20 species) and Sertung (16 species).

The other islands in the Sunda Strait, such as Sebesi, Sertung and Panaitan, played important roles as stepping stones for colonization of the Krakatau Islands from Sumatra and Java. Sebesi Island acted as stepping stone for the colonization of butterflies (Yukawa et al., 2000). However other studies suggested that Sebesi Island had a little role as a stepping stone for colonization of terrestrial birds, reptiles, bats, land molluscs or plants (Thornton et al., 2002).

Acknowledgments

The authors acknowledge generous contribution from Muhammad Azmi of Komodo Survival Program for his Komodo Dragon photo. Great appreciation is also extended to Wahyudi Amin of Kerandangan Natural Park at Lombok Island, as well as Muhammad

Fathurrozi of Biology Study Program, Faculty of Mathematic and Natural Sciences, Udayana University for their Rinjani Scops Owl photos. The authors would also like to thank Nurul Hidayat and Bisnis Indonesia for their generosity allowing us to use their aerial photo of Krakatoa eruption in December 2018.

Abstract

The Marshall Islands consist of 29 low altitude atolls comprising corals and foraminifera sand, which makes them vulnerable to natural disasters and climate change. The large amount of precipitation sustains the island's biodiversity (Whitehead and Jones, 1969; Yamaguchi et al., 2009). Majuro, the capital city of the Marshall Islands, has one of the longest human resident histories of all atolls worldwide, for more than 2000 years (Yamaguchi et al., 2009). Across the islands, the portmanteau biota of pigs, dogs, chickens, taro, and breadfruit were transported from European ancestors (Crosby, 1986). However, World War II left the islands covered with radioactive chemicals and heavy metals, the bioaccumulation of which has had adverse effects on plants, animals, and humans inhabiting the islands (Odum, 1971). Adverse effects of chemicals may be found in water, air, and food. Proper risk management is needed to handle these substances of war and modernization.

Introduction

Many coral reef islands exist worldwide. Coral reefs are divided into three groups, namely, fringing reef, barrier reef, and atoll. In the case of atolls, carbonate platforms have grown on sinking volcanic edifices (Darwin, 1842) and comprised an annular reef rim surrounding a central lagoon (Woodroffe et al., 1999) (Fig. 1). About 500 atolls are present around the world, most of which are located in the equatorial Pacific Ocean, which has a circumtropical climate zone (e.g., Fujita et al., 2009; Yasukochi et al., 2014).

The Marshall Islands consist of 29 atolls and five small coral islands that are spread over 1300 km east–west and 1500 km north–south and scattered irregularly in two vaguely defined chains that are named Ralik and Radak (Ratak) for the northwest to the south-east groups, respectively (Thomas, 1989; Yamaguchi et al., 2009). The total land area in the Marshall Island republic is ~181 km, and the total area including lagoons is about 11,664 km (Thomas, 1989).

Among atolls and islands, namely, Utrok, Kwajalein, Maloelap, and Majuro, radiocarbon dating of carbide was reported as 2000 years cal BP, which corresponds to the earliest age of settlement area on the high islands in East Micronesia (Yamaguchi et al., 2009).

Sea-level fluctuations in the Holocene triggered the formation of reef islands (Dickinson, 2003). As the sea levels rose, corals grew vertically to the surface of the sea so zooxanthellae could carry on photosynthesis; after the sea level stabilized around 2000 BC, the corals continued to grow laterally; this period lasted for about 2000 years (Fig. 2) (Dickinson, 2003). After the

Fig. 1 Developing stage of coral reef islands. Depending on the coral development and the degree of volcano subsidence, each stage is called fringing reef, barrier reef, and atoll.

Fig. 2 Reconstructed sea-level curve for the late Holocene in the Marshall Islands. Vertical green bar indicates the elevation differences between the present-day mean sea level (MSL) and modern microatolls. Data from Kayanne H, Yasukochi T, Yamaguchi T, Yamano H, and Yoneda M (2011) Rapid settlement of Majuro Atoll, Central Pacific, following its emergence at 2000 years CalBP. *Geophysical Research Letters* 38: L20405; Kench PS, Owen SD, and Ford MR (2014) Evidence for coral island formation during rising sea level in the Central Pacific Ocean. *Geophysical Research Letters* 41: 820–827.

late Holocene, the tropical Pacific sea level fell, exposing the mid-Holocene reef flats, and they now stand well above sea level (Dickinson, 2003, 2004). The “close-over date” signifies when the seawater surface at high tide falls below the top of the coral, triggering coral land formation; this close-over date in the Marshall Islands (Table 1) was reported to be 700 AD (Dickinson, 2009). The magnitude of highstand in the Marshall Islands and Kiribati was updated by Kayanne et al. (2011), Kench et al. (2014), and Yamano et al. (2017). Yamano et al. (2017) pointed out issues with dating samples based mainly on cemented coral rubble deposits, and they encouraged a re-examination of the timing and magnitude of the late Holocene sea-level high stand at Tuvalu, which suggested 2.3–2.4 m above the present sea level (Schofield, 1977; Dickinson, 1999, 2009) (Table 1).

Islands began to form after reef flats emerged above the sea level and wave energy was reduced (Yasukochi et al., 2014). Unconsolidated calcareous bioclastic sands and gravels (Fig. 3) deposited on the reef flats (e.g., Perry et al., 2011; Yasukochi et al., 2014).

After the core islets emerged, the earliest islanders established habitations at around 2000 BP in Laura on the Majuro Atoll (Yamaguchi et al., 2005, 2009) (see “Portmanteau Biota” section).

The Marshall Islands are geographically isolated from mainland (Yamaguchi et al., 2009). Their isolation from continental species pools increased endemism and also made these island ecosystems hypersensitive to the introduction of exotic species. Human transport (accidentally or intentionally, called the “transported landscape”) of portmanteau biota from Europe altered natural landscapes (e.g., Crosby, 1986; McNeill, 1994; Yamaguchi et al., 2009) (see “Portmanteau Biota” section).

In this review, we discuss the biogeography, unique history, and ecosystems of the Marshall Islands, and how the chemical risks have arisen as modern issues.

Biodiversity Trends of Flora

The flora of the Marshall Islands is divided into tropical forests, cultivation lands, and seagrass areas. The tropical forest area is divided into indigenous and planted flora.

Mixed broadleaf forest is the most popular and obvious type of vegetation in undisturbed areas in the Marshall Islands; typical broadleaf forest of *Tournefortia argentea*, *Guettarda speciosa*, *Pisonia grandis*, *Pandanus tectorius*, *Allophylus timoriensis*, *Cordia subcordata*, *Hernandia sonora*, and other less common species was observed in the inner land (Thomas, 1989). The Marshall Islands spread from the Taongi Atoll at lat. 14°41'N south to the Ebon Atoll at lat. 4°30'N, resulting in varied annual precipitation throughout the islands (see “Required Conditions for Biodiversity” section).

Table 1 Highstand magnitude, tidal range, and cross over date according to the data from Dickinson (2009)

Island	Highstand magnitude (m)	Tidal range (m)	Crossover date (CE)
Marshall Islands	1.1 ^a	1.6	700
Kiribati–Tungaru chain	1.0 ^b	1.5	1000
Tuvalu	2.3	1.6	1100
Tokelau	1.8	1.0	1000
Northern Cook Islands	1.1	0.6	900
Northern Tuamotu Archipelago	1.0	0.3	900

The data of highstand magnitude in Marshall Island^a and Kiribati^b were acquired from Kayanne et al. (2011), Kench et al. (2014), and Yamano et al. (2017), respectively.

Fig. 3 Calcareous bioclastic materials, which constitute the sediment of coral reef islands. (A) Foraminifera (*Calcarina* spp.) and (B) Coral gravels and shells.

Mangrove vegetation exists in some of the areas of heaviest rain, such as Jaluit, Arno, and Ailinglapalap Atolls in the south (Thomas, 1989). Northward mangrove basins, especially *Bruguiera*, are situated in low and wet inland areas; in some cases, the Marshallese planted the propagules of *Bruguiera*, forming dense, pure stands; however, they did not spread in areas that have no connection with the sea (Thomas, 1989).

In some cases, indigenous plants survived as windbreaks. The windward sides of the islands are left more or less intact to protect the coconut plantations and taro pits from salt spray, providing a reservoir of natural diversity and food and copra production (Thomas, 1989).

Among cultivated trees, coconut and breadfruit were significant in pre-European traditional subsistence (Rappaport, 1963). People preserved breadfruit into a semifermented paste called “Bwiro,” which is still produced in quantity and regarded as a succulent addition to the post-breadfruit season diet (Dye, 1987). Traditional pit cultivation is also popular in the Marshall Islands. Phytogeographical studies indicated that similar to banana and breadfruit trees, wet taro can be cultivated on atolls where the mean annual precipitation is more than 2000 mm (e.g., Stoddart, 1992; Fosberg, 1984; Yamaguchi et al., 2009). The pits for taro cultivation are dug in the interiors of the large islands (Yamaguchi et al., 2009). Pits are filled with decomposing vegetable matter, such as *Colocasia* and *Cyrtosperma*, and the most edible taro genera, sugar cane, and a few plants useful as food and medicines are planted (Thomas, 1989).

The cultivation of aroid crops on atolls was limited to areas of low salinity, as well as sites modified by excavation for composting (Rappaport, 1963). The transformed areas were generally small, although primary productivity in taro pits was probably higher than that in any unmodified portion of the ecosystem (Rappaport, 1963). Among the root crops, tubers of *Cyrtosperma*, cultivated for its edible corm, have the highest carbohydrate content per unit among the aroids and are able to hold up against high water levels or flooding (Yamaguchi et al., 2009). This species is adaptable to a fluctuating water table (Lambert, 1982), explaining why *Cyrtosperma* has been the main aroid grown across the Marshall Island atolls (Yamaguchi et al., 2009). However, in Majuro, *Cyrtosperma* pits have been abandoned. The introduction of pigs led to a decrease in *Cyrtosperma* and *Tacca leontopetaloides* because of the animals’ rooting (Dye, 1987).

The copra tree industry has grown since the Germans first occupied the atoll in 1885 (Rappaport, 1963) and supports some aspects of the atoll’s economy (Riley, 1987; Kai, 2006). The present flora of the atoll began with the German occupation in the Marshall Islands in 1888, with the large increase in coconut plantations (Dye, 1987).

Sea grasses are rare in the Marshall Islands; only two stands of *Thalassia hemprichii* and *Cymodocea rotundata* are found in the shallow water of Ujelang, Ailinglapalap, and Majuro Atolls (Thomas, 1989). In particular, *C. rotundata* has flourished on lagoon shoals around the central part of the Laura Island in Majuro. *Halimeda* spp., a calcareous green alga with flake-like segments, constitutes the most abundant sediments of the lagoon (Thomas, 1989).

Biodiversity Trends of Fauna

The natural diversity of the Marshall Islands is higher than the dry northern atolls (Thomas, 1989). Marine and forest animals received commercial attention in the 19th century; for example, a remarkable market existed for sea cucumbers (Class: Holothuroidea) in China (McNeill, 1994).

For island-specific biota, nonisland creatures often become a threat. For example, accidentally introduced rats onto the uninhabited Taongi Atoll from support boats, visiting yachts, and fishing birds quickly decimated native bird populations (Thomas, 1989). Pigs, fowl, dogs and cats, transported from other continents, are abundant on the atoll today (see “Portmanteau Biota” section).

Regarding the characteristics and habitats of birds, we summarize the reports of Thomas (1989) and Hatheway (1953).

Birds are the most remarkable group of terrestrial animals in the Marshall Islands (Thomas, 1989). Three major feeding habitat categories of seabirds in the Marshalls are coastal (beaches, reefs, and lagoons), offshore (near islands or atolls), and pelagic; ranges may overlap or may vary by season (Thomas, 1989).

Seventy resident bird species (31 seabird species and 39 land and fresh water birds) have been recorded in the Marshall Islands (Thomas, 1989). Migrant shorebirds, such as white terns (*Gygis alba*) and noddies (*Anous sp.*), are usually found away from human activity. With no human habitation and few visitors, the northern Ralik Island chain has become an important breeding place for these species (Thomas, 1989).

Large numbers of great frigate birds (*Fregata minor*) and red-footed boobies (*Sula sula*) were observed on the atoll; red-footed boobies are the dominant nesting species, with an estimated 500–1000 individuals on Bikar, 250 on Jabwelo, and 150 on Almaní (Thomas, 1989). The groves of *Pisonia* trees serve as rookeries for numerous fish-eating seabirds on sandy soils near the lagoon (Hatheway, 1953). Destruction of *Pisonia* forests leads to a decrease in bird populations here (Thomas, 1989).

Hatheway (1953) reported that birds appeared to prefer branches of the *Pisonia* to those of any other trees; for example, the tops of large *Pisonia* trees on Arno Atoll were always crowded with flocks of roosting and nesting seabirds. The fruits of *P. grandis* are glutinous and adhere to the feathers of wide-ranging seabirds, which roost and nest in its branches (Hatheway, 1953). The presence or absence of local phosphate deposits in the interiors of many islands is probably not a coincidence (e.g., Hatheway, 1953; Mulder and Ellis, 2010; Ito et al., 2018a). Large flocks of roosting seabirds enrich the soil with their droppings (Dye, 1987). The droppings of these birds would eventually result in the formation of phosphatic rock, as observed on the Takleb Island; present local deposits of phosphatic rock may well coincide with former *Pisonia* groves (Hatheway, 1953). The islets, Takelib and Nami had been traditionally reserved as “bird islets” until 1876 and have expensive deposits of phosphatic rock underlying shallow humic topsoil (Dye, 1987).

However, when sea birds on coral atolls were driven out by human settlements, the soils could no longer be replenished with the phosphate and nitrate contents of guano (Fosberg, 1953; Hatheway, 1953). Fosberg (1953) pointed out that another possible cause of the loss of additional phosphate from island ecosystems could be the export of large quantities of phosphorous-rich copra.

The Marshall Islands are also famous for coconut crab (*Birgus latro*), endangered Hawksbill turtles (*Eretmochelys imbricata*), and threatened green turtles (*Chelonia mydas*) (Thomas, 1989; IUCN, 1982, 1983). The nearshore habitats support various species of fish, of which diversity is similar between the northern and southern Marshalls (Randall and Randall, 1987). Small skinks (*Scincella lateralis*), geckos (*Gekkonidae*), insects, and Polynesian rats (*Rattus exulans*) are found across the islands. Polynesian rats are common on Bikar and Jabwelo (Thomas, 1989).

Nostoc is a bacterial species that can fix nitrogen serving as a nutrient source for pioneer ecosystems on atolls, of which abundant colonies appear on coral sand flats and also on the flat exposure of lithified limestone after rain or heavy dew, drying black when exposed to the sun (Thomas, 1989).

Portmanteau Biota

The ancestors of the inhabitants of islands brought pigs, dogs, chickens, taro, breadfruit, and bananas from their original lands and recreated the scenery of their homes in their new landscapes; thus, a “transported landscape” has been created by these “portmanteau biota” (Anderson, 1952; Crosby, 1986; McNeill, 1994; Yamaguchi et al., 2009), as explained below.

Most people in Micronesia, including in the Marshall Islands, speak a language belonging to Nuclear Micronesian, one of the proto-Oceanic subgroups closely correlated with the eastward expansion of the Lapita cultural complex (Yamaguchi et al., 2009). Lapita peoples practiced distinctive irrigation in Melanesia, and cultivated root vegetables, *Colocasia* and *Cyrtosperma*, in natural squashy swales located at the back of the beach terraces where their homes are also located (Kirch and Hunt, 1997; Kirch and Lepofsky, 1993).

The islands where they moved were targets of environmental disasters of one sort or another, such as drought, cyclone, tsunami, volcanic eruption, and flood (McNeill, 1994). Faced with these disasters, island settlers tried to turn their new homes into familiar and manageable landscapes (McNeill, 1994). They created suitable “transported landscapes” (Anderson, 1952) to the best of their abilities by importing what Crosby had called a “portmanteau biota” (Crosby, 1986). When people first encountered the strange environment of the isolated atolls, they brought seed tubers and the knowledge to cultivate swamp taro in hydromorphic terrain (Yamaguchi et al., 2009). This landscape has continued for about 2000 years, one of the longest human histories in atolls (Yamaguchi et al., 2009).

“Portmanteau biota” also caused an ecological homogenization based on a small number of widely distributed species (McNeill, 1994). For example, the Polynesian portmanteau biota consisted dominantly of three or four animals, such as rat, dog, chicken, and pig, and several edible plants, such as coconut, taro, and breadfruit, that have been widespread over the Pacific (McNeill, 1994).

Regular or even sporadic interisland voyages triggered the spread of countless species, including parasites, insects, rodents, and other small land predators, and weeds and other plants whose seeds could be accidentally lodged and transported in canoes (Murdoch, 1963). These species are transplanted to islands, where their respective ecological niches were either unoccupied or occupied by weak autochthonous forms and where the forms they preyed on were unprotected and vulnerable. Therefore, introduced species repeatedly wreaked havoc on the native fauna and flora, extinguishing native species prior to documentation of their range and distribution (Murdoch, 1963).

Indigenous flora primarily survived in unoccupied areas (Murdoch, 1963), although some species survived under or within plantations (Rappaport, 1963). Even when exotic forms were not rejected, some were established less easily and less extensively than others (Rappaport, 1963). The establishment of introduced root crops, such as taro-like plants, generally required painstaking cultivation (Rappaport, 1963). Breadfruit cultivation was possible but limited by calcareous soil (Catala, 1957) and by the sensitivity of the trees to salt water spray or inundation (Fosberg, 1953). Some animals, such as rats, established readily (Rappaport, 1963).

The portmanteau biota has a second phase. The initial arrival of Europeans and their portmanteau biota was a disaster for lowland organisms and soils across the islands (Fosberg, 1992; McNeill, 1994). Many native species became extinct, and others

found their domains reduced by the onset of the invaders (Fosberg, 1992). For European residents, transporting exotic species, such as pineapple, pumpkin, potato, and cattle, as well as pet dogs and cats, became a way of life (Yamaguchi et al., 2009).

Humans are also an exotic biotic element in island ecosystems (Rappaport, 1963) with population density increasing over the last several decades (Spennemann, 1992). Currently greater than 20,000 people live in Majuro (Osawa et al., 2010). The population center moved to the east end of the atoll after World War II (Xue, 2001). This east area called Djarrit-Uliga-Delap (D.U.D) is composed of three islets. D.U.D contains 70% of the total population of Majuro (Spennemann, 1992). The remaining 6500 people live in less urbanized areas on the north and west sides, in Laura, Calalen, and Jelto.

Thomas (1989) suggested that increasing development activities would lead to the overexploitation of resources, the destruction of habitats, loss of key species, and breakdown of natural systems that have come before the environmental disasters that have occurred in other parts of the world. Severe soil erosion is an example of damage caused by development activities and is attributed to poor land use practices and forest exploitation; reefs and beaches are destroyed or degraded by siltation and dredging construction materials; lagoons are contaminated by urban wastes; and fisheries are depleted because of overexploitation and illegal fishing practices (Thomas, 1989).

Many species are threatened with extinction due to exploitation and environmental pollution. Here, the rate of species loss is high due partly to the small and isolated nature of the island habitats; in most cases, the lost species and their habitats are irreplaceable to biological diversity in the national, regional, and global viewpoints (Thomas, 1989). Intensive urbanization of the population, as seen in D.U.D (Xue, 2001), leads to overfishing and loss of marine biodiversity (Thomas, 1989).

Required Conditions for Biodiversity

Several factors contribute to terrestrial biodiversity, such as atoll size, height above sea level, vulnerability to sea-level rise and storms, precipitation, insufficient groundwater, and distance from mainland (Wiens, 1962; Niering, 1963; Whitehead and Jones, 1969; Stoddart, 1992; Yamaguchi et al., 2009).

In general, in atolls, transportation across open water and accessibility to land is difficult. Simberloff (1974) suggested that even the simplest equilibrium model indicates that distant islands ought to have fewer species than near islands, and small islands ought to have fewer species than large ones. Thus, the biota of an island chain reflects the biotic diversity of the source region, the island size, and the distance from the source (Whitehead and Jones, 1969).

The annual and seasonal precipitation differs across the Marshall Islands due to the trade-winds zone extending from west to east and the north to south gradient of increasing rainfall (Thomas, 1989; Yamaguchi et al., 2009). The northern atolls, such as Taongi, have an effectively semi-arid climate, with 750–1000 mm annual precipitation, whereas, the southern atolls, such as the Majuro and the Ebon, have 3700–5000 mm annual perception because they are within the equatorial high rainfall belt (Thomas, 1989). This range of precipitation is shown in Fig. 4 (Stoddart, 1992).

Rainwater soaks into the underground (up to ~20 m) because of the highly permeable coarse and porous sand made of unconsolidated bioclastic sands, such as foraminifera and coral gravel (e.g., Perry et al., 2011; Yasukochi et al., 2014). Subsequently, the rainwater floats on the seawater, and this floated water has a convex lens-like appearance and is called the “freshwater lens” (Hamlin and Anthony, 1987; Anthony et al., 1989). The gradient of this lens affects plant biodiversity, as influenced by local precipitation (Yamaguchi et al., 2009).

Laura in Majuro Atoll is famous for its large freshwater lens, which is as large as 182 ha (e.g., Hamlin and Anthony, 1987; Anthony et al., 1989; Yamaguchi et al., 2009). The survey in Laura revealed that the upper fine sand unit is about 25 m thick on the lagoon ward edge and 16 m even inland; this thickness and relatively low permeability prevents salty seawater from mixing upward with the freshwater (Underwood et al., 1992). Yamaguchi et al. (2009) indicated that one of the essential ingredients for human habitation seems to be the potential for cultivating wet taro in agricultural pits maintained by sufficient freshwater resources.

The increase in the number of species will not be significant unless the island size is large enough to maintain a freshwater lens (Whitehead and Jones, 1969). A larger island also provides crop protection from sea salt spray. Fresh ground water, which is

Fig. 4 Annual average precipitation in major atolls. Modified from Stoddart DR (1992) Biogeography of the tropical Pacific. *Pacific Science* 44: 276–293.

Fig. 5 Correlation between the number of species and island size. Modified from Whitehead DR and Jones CE (1969) Small islands and the equilibrium theory of insular biogeography. *Evolution* 23: 171–179.

essential for the growth of staple cultigens, was limited to only a few of the atoll's many islands (Dye, 1987). At least 1.4 ha is needed to store rainwater in the freshwater lens to allow a variety of salt-intolerant species to be established (Whitehead and Jones, 1969). Fig. 5 shows that a correlation exists between island size and (i) total number of species, (ii) strand species, (iii) nonstrand species, and (iv) introduced species. The number of species increases around 1.4 ha. The total number of this species available in the "species pool" is low; seldom more than 20–25 have been observed for any atoll system (Whitehead and Jones, 1969).

Nonstrand species that have low resistance to salt water are normally absent from the small islets (Whitehead and Jones, 1969). Nonstrand species can be established only when the islands are large enough to maintain water and possess high ecological diversity; they increase rapidly when the islets are sufficiently large to hold a freshwater reservoir, and introduced species also start to appear on islands that are large and diverse enough to be useful to man for both agriculture and habitation (Whitehead and Jones, 1969).

The area–diversity curve could be highly exaggerated by the introduced species, suggesting that the islands have been deeply affected by humans through habitation, maintenance of taro, breadfruit, and coconuts, and by the events of World War II (Whitehead and Jones, 1969).

The oligotrophic and the high pH of calcareous sand can also limit vegetation diversity. Fig. 6 depicts the depth profiles of major elements calcium (Ca) and magnesium (Mg), trace elements aluminum (Al), phosphorous (P), and iron (Fe), showing that Ca concentration remained almost constant and had the highest concentration among all elements (Ito et al., 2018a). The concentrations of Al, P, and Fe increased toward the surface in the three islands in Majuro; however, the concentration was markedly low in the rhizosphere. Among these trace elements, only P was found in high concentrations (Ito et al., 2018a), which likely originated from bird feces (e.g., Mulder and Ellis, 2010; Ito et al., 2018a).

Fig. 6 Soil pH and concentration of elements in the sediment of the Majuro Atoll. Data from Ito L, Omori T, Yoneda M, Yamaguchi T, Kobayashi R, and Takahashi Y (2018a) Origin and migration of trace elements in the surface sediments of Majuro Atoll, Marshall Islands. *Chemosphere* 202: 65–75; Ito L, Yamaguchi T, Kobayashi R, Terada Y, and Takahashi Y (2018b) Influence of acidification on carbonate sediments of Majuro Atoll, Marshall Islands. *Chemistry Letters* 47: 566–569.

The surface layer pH was neutral and soil acidification was observed (Ito et al., 2018b). Overall soil pH ranged from 8 to 9. This high pH lowers the solubility of the low concentrations of Fe (e.g., Lindsay and Schwab, 1982); plant diversity is limited under this oligotrophic environment with high soil pH.

Chemical Risks

Adverse anthropological impacts in the form of chemicals (e.g., Tokai et al., 2002) have become points of concern. A rare element can become a biological concern if it forms a highly toxic metallic compound (e.g., Itai et al., 2014) or a radioactive isotope (e.g., Takahashi et al., 2017). Heavy metal contamination occurs from industrial products dumped directly into the environment without proper waste treatment plants; this problem has become a big issue on Funafuti in Tuvalu, where the population density is high, modernization is progressing, but garbage disposal technology is poor (Fujita et al., 2013, 2014). On the other hand, the ground-water contamination has stemmed from heavy metal co-precipitate on apatite formed by the chemical reaction occurring at the surface of calcareous foraminifera sand from the phosphorous from bird feces in Majuro Atoll (Ito et al., 2018a).

Other chemical risks related to residual radioactive nuclides have still remained because of the nuclear tests conducted after World War II around Bikini and Eniwetok Atolls.

Nuclear testing released a remarkable quantity of radioactive nuclides to the environment starting in 1946 when the United States set off a bomb at Bikini Atoll. The first hydrogen bomb test called Operation Greenhouse was conducted in 1952 on the neighboring Eniwetok Atoll (McNeill, 1994). Jackson (1969) reported that the tests killed off the rat population of the atoll. Most fission products in nuclear weapon tests involve elements, such as radioactive strontium (Sr) or cesium (Cs), that are not essential for life and have been added to the biosphere on a global scale (Odum, 1963, 1971).

These radioactive isotopes are concentrated in the food chain and eventually incorporated into the biomass (Odum, 1971). Organisms generally tend to accumulate nutrients, so concentrations within the biomass often exceed the concentration in the immediate physical environment (Odum, 1963). Among radioactive materials, the risk of fission product ^{90}Sr , which is particularly dangerous to man and other vertebrates, was enumerated by Odum (1963, 1971) as follows:

- (i) Global reach: ^{90}Sr is a common component of atomic fallout and atomic wastes worldwide.
- (ii) Long half-life: ^{90}Sr loses its radioactivity slowly (in technical terms, it has a half-life of 28 years) in contrast to many fission products that decay to harmless levels in a few hours or days.
- (iii) Similarity with Ca: ^{90}Sr behaves chemically like Ca, an abundant and biologically important element, and ^{90}Sr follows natural (nonradioactive) strontium and calcium into biogeochemical cycles.
- (iv) Easy absorption: ^{90}Sr is taken up by plants more readily than most fall-out materials directly via foliage absorption, soil, and water.
- (v) Bioaccumulation for fatal parts: when taken in with food by man and vertebrates, ^{90}Sr becomes concentrated and retained by the bone in close proximity to blood-making tissue in the bone marrow, which is rapid dividing cell area and especially sensitive to radiation damage; as such, mammals are considerably sensitive to low doses of ^{90}Sr (Gambino and Lindberg, 1964; Golley et al., 1965).

For example, ^{90}Sr from fall out assimilates into humans and animals readily through the grazing food chain in ecosystems, where precipitation is large (Odum, 1963). Also, a large proportion of fallout will enter food chains in nutrient-poor environments (Odum, 1971). The Marshall Islands, which have geological properties that meet these two conditions, requires further care and concern given the risks of these radioactive materials.

Radionuclides that enter marine food chains are rather strikingly different from those that enter terrestrial food chains (Palumbo, 1961). For example, soluble fission products, such as ^{90}Sr and ^{137}Cs , were found in the highest amounts in land plants and animals, whereas two types of elements shown below transfer in the highest amount to marine organisms; (i) ones that are induced by neutron bombardment and form strong complexes with organic matter such as cobalt (Co)-60, Fe-59, zinc (Zn)-65, and manganese (Mn)-54, and (ii) those that are present in particulate or colloidal form (cerium-144, praseodymium-144, zirconium-95, and rhodium-106) (Odum, 1971).

The effects of low-level chronic doses are difficult to measure because of the long-term genetic and somatic effects that may be involved (Odum, 1971). Before the first atomic tests, residents evacuated, and many returned early in the 1970s after the official safety declaration; however, they were re-evacuated from the islands when this declaration was doubted in the late 1970s, and the islanders' health status became a controversial issue (McNeill, 1994). From 1993 to 1997, medical and epidemiological studies were conducted via the Marshall Islands Nationwide Thyroid Disease Study. Takahashi et al. (1997, 1999) found that people who lived in Majuro in the 1950s and later had the highest prevalence of thyroid nodules, and a significant proportion of the Marshallese population suffers from moderate iodine deficiency based on the World Health Organization (WHO) criteria on inorganic iodine (World Health Organization, 1994). As a result of urine examination, 22% of the 309 adults in Majuro Atoll (184 females, median age of 50 years; 125 males, median age of 43 years) met the WHO criteria of moderate iodine deficiency and 1% of them met the criteria of severe deficiency, whereas a high ratio of the deficiency was observed in additional smaller groups (53 adults) in the Likiep Atoll, where lifestyles are based on traditional ways, such as fishing and traditional food-gathering practice; 48% showed moderate iodine deficiency and 13% adults showed severe iodine deficiency (Takahashi et al., 1999) (Fig. 7).

Fig. 7 Percentage of adults classified in each category of urinary iodine excretion in the Majuro and Likiep Atolls. Based on the data of Takahashi T, Fujimori K, Simon SL, Bechtner G, Edwards R, and Trott KR (1999) Thyroid nodules, thyroid function and dietary iodine in the Marshall Islands. *International Journal of Epidemiology* 28: 742–749.

These results and the dietary review in the Marshall Islands (Dignan et al., 1994) suggest that fish is the main source of dietary iodine; traditional lifestyle may cause iodine deficiency because the Marshallese should consume more than 130 mg of iodine only by fish, which would amply cover the requirement of the body (Takahashi et al., 1999) and should be related to the food chain and bio-accumulation. Although the moderate degree of iodine deficiency of the Marshallese is not severe enough to cause any clinical or biochemical signs of thyroid hormone disorder, they may have suffered from iodine deficiency for a long time (Takahashi et al., 1999).

Radioactive chemical risk has remained even after more than 50 years that bomb tests have been conducted and remains as one of the major problems in the Marshall Islands. Thus, “radioactive wastes must be anticipated, monitored and controlled” (Odum, 1971).

Conclusions

The Marshall Islands were formed via sea-level fluctuations in the late Holocene (Dickinson, 2003). The ancestors of the islands, the Lapita people, had come soon after the emergence of the islands (e.g., Kirch and Hunt, 1997; Kirch and Lepofsky, 1993; Kayanne et al., 2011). In the case of Majuro in the Marshall Islands, the “transported landscape” has lasted for ~2000 years (Yamaguchi et al., 2009) with abundant rainfall and sufficient land area (1.4 ha or more) to provide a high-quality freshwater lens (e.g., Whitehead and Jones, 1969; Stoddart, 1992). These important factors contributed to the sustainability of life on the islands. Introduced pigs, chickens, and dogs and cultivated plants, such as taro, breadfruit, and bananas, support people (Yamaguchi et al., 2009). These “portmanteau biota” had been transported from the original lands of the ancestors (e.g., Crosby, 1986; McNeill, 1994). Thus, many flora and fauna have flourished on the Marshall Islands with conditioned natural environment, and we can even encounter the endangered species, such as green turtles (*C. mydas*) (Thomas, 1989). However, the Marshall Islands faced severe chemical risks after World War II because of a number of nuclear bomb tests and the heavy metals in industrial products (e.g., McNeill, 1994; Fujita et al., 2014). Given that the islands have no facilities to treat these chemicals, people on the islands have had to face the risks associated with accumulated radioactive chemicals and heavy metals (e.g., Odum, 1971; Fujita et al., 2014; Ito, 2018). These chemicals have bioaccumulated in food sources (Odum, 1963, 1971). The risks posed by these chemicals are understudied.

Acknowledgments

I am grateful for the Marshall Islands Environmental Protection Authority (RMIEPA) and the staffs in Majuro and Japan who have cooperated on the fieldwork related to my study and this review. This work was supported by the Environment Research and Technology Development Fund (S17-1(2)) of the Environmental Restoration and Conservation Agency of Japan, and Grants-in-Aid for scientific research from the Ministry of Education, Culture, Sports, Science and Technology of Japan (18H04134).

Abstract

In the Madrean Sky Islands, deserts meet mountains in a patchwork of multiple biomes including desertscrub, grassland, woodland, and forest. The Sky Islands comprise the Madrean Archipelago, one of Conservation International's 35 Global Biodiversity Hotspots, and contain over 7000 species of plants and animals (Desert Landscape Conservation Cooperative 2019). This unique landscape faces complex threats and stressors, including longer and more extreme droughts, spatial and temporal changes in precipitation, increased groundwater withdrawal, invasive species, changing fire regimes, and expanding human communities. A collaborative group, the Madrean Transboundary Watersheds Landscape Conservation Design (Madrean LCD), has developed for the purpose of integrating social values with ecological goals to promote resilience in the Sky Islands. This article describes the Madrean Sky Islands and the process, lessons learned, and ongoing conservation priorities of the Madrean LCD.

The Madrean Sky Islands: Where Deserts Meet Mountains

Sky Islands are characterized by mountain "islands" surrounded by desert or grassland "seas." The Madrean Sky Islands comprise the ecoregion surrounding the Madrean Archipelago, a chain of mountains that connects the temperate Rocky Mountains to the north and the tropical Sierra Madre Occidental in the south. These 65 isolated mountains vary between 915 and 3300 m in elevation, rising out of the Sonoran Desert, Chihuahuan Desert, and Great Plains grasslands (Sky Island Alliance, 2019a). Higher elevations receive more precipitation than lower elevations, with some mountaintops receiving four times the annual rainfall of their

surrounding basins ([Banister et al., 2014](#)). Each mountain provides multiple environments where plants, animals and habitats connect and blend together—not in a single biome, but in a patchwork of biomes that vary according to elevation and aspect. In the Madrean Sky Islands, deserts meet mountains, jaguars meet black bears, and cacti meet cottonwood trees ([Sky Island Alliance, 2019a](#)) (Figs. 1 and 2).

Ecology of the Sky Islands

Biodiversity

The Madrean Sky Islands contain some of the most rugged and remote lands in the American Southwest, and feature some of the highest levels of biodiversity in the world ([Sky Island Alliance, 2019a,b](#)). The Madrean Archipelago ecoregion has been recognized as one of 35 Global Biodiversity Hotspots by Conservation International, and more than 7000 species of plants and animals, including over half the bird species in North America, can be found here ([Desert Landscape Conservation Cooperative, 2016](#)) (Figs. 3 and 4).

Biomes

The Madrean ecoregion is comprised of convergences of biomes and transition zones. At the base of the Madrean Sky Islands are warm, arid desert and scrubland dominated by cacti, succulents, and shrubs. Progressing up a mountain, grassland, woodland, pine forest, mixed conifer forest, and sub-alpine forest can be found, as well as wetter areas such as riparian forests and wetlands ([Debano, 1999](#)). Each Sky Island mountain is a vertically integrated succession of ecosystems that support the inhabitation and migration of a great and unique variety of species; the ability of organisms to migrate vertically as temperatures increase makes the Sky Islands important climate refugia ([Misztal et al., 2016](#)) (Figs. 5 and 6).

Riparian Ecosystems

In addition to the mountains that dot the Madrean ecoregion, a distinguishing landscape feature is the ribbons of streambeds that flow down mountains and through desert basins. Water may be present at the surface of these streambeds year-round, but many watercourses in the Sky Islands have only ephemeral flows. Water is also available at springs and wetlands, or cienegas ([Sky Island Action, 2008](#)). Regardless of whether surface water is present, areas where groundwater is close to the surface (i.e., riparian zones) are strikingly different from the surrounding drylands. Large trees such as cottonwood, willow, sycamore, and ash, as well as various shrubs, forbs, grasses, algae, and micro-organisms, are prevalent in riparian zones but in no other Sky Island communities. The dense vegetation stabilizes streambanks, slowing erosional processes and providing places for seed banks. The shade, litter, bark, and seeds from dense riparian vegetation support wildlife, which find respite in riparian areas from the warmer uplands. Riparian zones support a great variety and diversity of organisms; for example, the 230-km stretch of the San Pedro River alone contains more native vertebrate species than Yellowstone National Park ([Sky Island Alliance, 2019a,b](#)). Riparian areas also serve as corridors for migration or dispersal of numerous plant and animal species, as well as water, nutrients, and sediment. Riparian zones are a critical conservation resource in the Sky Islands ([Fig. 7](#)).

Fig. 1 The Madrean Archipelago, as viewed from the northern aspect of the Santa Catalina Mountains of southeastern Arizona, United States.

Fig. 2 The mountain ranges of the Madrean Sky Island ecoregion of the United States and Mexico (Sky Island Alliance, 2019b).

Fig. 3 Each Sky Island mountain is different, and their biota are largely impacted by elevation. For example, peaks of the Santa Rita Mountains, at approximately 280 m, are sub-alpine environments; while peaks of the Drought Mountains, at approximately 250 m, feature woodland communities.

Fig. 4 The Dragoon Mountains of southeast Arizona, United States contrast in elevation and geology (and therefore ecology) from the Santa Rita Mountains, only approximately 48 km (30 miles) away.

Fig. 5 Sonoran Desertscrub communities occur at low elevations surrounding Sky Island mountains.

Connectivity

Another asset of the Sky Islands for supporting major ecological functions is the connectivity of wildlife habitat. Many species migrate vertically within individual mountain ranges (including among and between riparian zones) to accommodate daily and seasonal environmental variations, while other species move between ranges. Animals such as mountain lion, jaguar, and bighorn sheep move frequently across ranges in pursuit of food or mates, and the absence of barriers between ranges allows populations to flourish. In addition, pollinators such as butterflies and bats migrate through the Sky Islands, and require habitat and forage to serve their function. It is important that wildlife corridors are considered in planning for infrastructure projects, urban development, and other human uses.

Geography and Human Uses

Human Communities

The Madrean Sky Islands span four states in the United States and Mexico, covering a patchwork of protected and unprotected public and private lands; and are interspersed by the cities of Tucson, Sierra Vista, and Nogales, Arizona; Silver City, New Mexico;

Fig. 6 Oak Woodland (foreground) transitions to Mixed Conifer Forest (background) in the Santa Rita Mountains.

Fig. 7 Winter precipitation in 2019 contributed to high surface flows in riparian zones of the Santa Catalina Mountains.

and Nogales, Hermosillo, and Magdalena, Sonora. In the United States, the majority of Sky Island mountain ranges are part of the Coronado National Forest, which hosts the greatest number of threatened and endangered species of any United States National Forest ([Sky Island Alliance, 2019a,b](#)). In Mexico, the Sky Island mountains and low desert valleys are largely a mixture of private ranches, *ejidos* (communal land used for agriculture), and *Reserva Forestal Nacional* (National forest reserves) ([Sky Island Alliance, 2019a,b](#)).

Human Use

Because they are so diverse, the Sky Islands have supported various human uses throughout history. Humans have continuously inhabited and farmed some areas since as early as 10,000 BCE, and one of the most advanced ancient irrigation systems in North America was built in the Santa Cruz River valley ([Potteiger, 2017](#)). Modern irrigation systems and long growing seasons have

supported extensive farming in the region (Banister et al., 2014). The grasslands between mountains have also supported centuries of ranching, and much of the Sky Island grasslands are still being utilized today for cattle production (Mizstal et al. 2017). Mining is another common industry that has sporadically supported towns and camps throughout the region (Banister et al., 2014). The Sky Islands have also become increasingly important for outdoor recreation; the variety of climates they offer support hiking, horseback riding, camping, birding, and other activities year-round (Coronado National Forest Recreation, 2019). The southernmost ski resort in the United States is located in the Santa Catalina mountains of southern Arizona, the top of which periodically receives enough winter snow for skiing, and the bottom of which is surrounded by Sonoran desertscrub as well as the Tucson metro area (Fig. 8).

Stressors and Threats in the Sky Islands

Between human uses and environmental factors, the Sky Islands face complex threats, including longer and more extreme droughts, spatial and temporal changes in precipitation, increased groundwater withdrawal, invasive species, more frequent and intense fire events, and expanding human communities (Misztal et al., 2016). Many of these threats are interrelated; for example, warming temperatures, decreasing water availability, and the spread of invasive species have caused ranchers to change their cattle rotations and farmers to alter their crops and growing practices. Urban development areas have altered hydrologic flows, water quality, and riparian systems. Decades of fire suppression, hotter temperatures, encroachment of invasive species, and drought have combined to create fuel conditions that support more severe wildfires (Patterson, 2016). Because of the diverse ecological communities that intersect in the Sky Islands, it is especially important to understand human, biological, geological, hydrological, and climatological relationships when managing issues and threats (Fig. 9).

Collaborative Conservation in the Sky Islands

The Need for Large-Landscape Conservation

With a multitude of environmental and social factors impacting the Sky Islands, conservation issues are manifested at much larger scales than those of individual management areas (Comer et al., 2013; Garfin et al., 2014). It is imperative to address these issues at the scale of large landscapes because they transcend existing jurisdictions and institutions (McKinney et al., 2010). Responding to these stressors requires coordinated planning and action at a scale that is relevant to ecological and evolutionary processes. To support conservation at the appropriate scale for effective results, a network of 22 Landscape Conservation Cooperatives (LCCs) was established by the US Department of Interior in 2010 to build systematic large-landscape conservation networks (Jacobson and Robertson, 2012). These LCCs were designed to facilitate collaboration across jurisdictional boundaries, developing shared conservation priorities and science needs, and creating strategies to be implemented through partnerships (National Academies of Sciences, Engineering, and Medicine, 2016).

Fig. 8 The grasslands surrounding Dripping Rock Mountains are used for livestock grazing.

Fig. 9 This photo depicts two interacting stressors on Sky Islands: invasive species and human development. Grasses such as Lehmann's Lovegrass (*Eragrostis lehmanniana*) have invaded Sonoran Desertscrub ecosystems. When the invasive grasses carry fire to these communities, they endanger species such as Saguaro cactus (*Carnegiea gigantea*) that are not fire-adapted. This location, the Santa Catalina Mountains, is surrounded by the city of Tucson, Arizona, which brings many recreationalists who can easily transport seeds of invasive species. However, with proper management, public education, and collaboration, the negative effects of human presence can be minimized.

Landscape Conservation Design

One of the primary ways to achieve the goals of LCCs was through the collaborative development of Landscape Conservation Designs (LCDs). LCDs are groups that involve the integration of societal values with ecological goals to describe where conservation can best be applied to support a resilient landscape. They adopt an iterative, collaborative, and holistic process to create strategic and spatial products that provide information, analytical tools, maps, and strategies to achieve landscape goals collectively held among partners (Desert Landscape Conservation Cooperative, 2016). In 2016, the Madrean Transboundary Watersheds LCD (Madrean LCD) was formed to support the resiliency of the Sky Islands across their diverse watersheds in the face of complex stressors.

Madrean Watersheds Landscape Conservation Design: Process, Outcomes, and Products

Process Summary

Genuine partner-driven collaboration is a foundational aspect of the Madrean LCD. From the outset, the effort has been based on partner priorities and management realities (rather than top-down directives). The LCD process, has included establishing a shared vision and goals; gathering existing plans, projects and data; identifying high-priority challenges and stressors; discussing actions and strategies for supporting climate resiliency; and iteratively engaging partners in developing tools that support their efforts.

Shared Values and Goals, Information Gathering, and Challenges

Preliminary discussions related to the Madrean LCD began in late 2015 with initial gatherings of partners from agencies, organizations, and institutions of the United States and Mexico in a series of bi-national workshops in Tucson, Arizona, Aguascalientes, Mexico and Alpine, Texas. In total, these gatherings were attended by over 140 participants from 45 different agencies and organizations (Desert Landscape Conservation Cooperative, Alpine Workshop Report 2016). In this preliminary stage, partners worked to identify shared values, pressing challenges, and stressors across the landscape, as well as gather relevant existing plans and information. These workshops built the foundation for Madrean LCD priorities and products.

Establishment of the Coordinating Team

As a central point for communication and guidance for the LCD, the Madrean Watersheds Coordinating Team was created in early 2016, comprising agencies, organizations and researchers from across the region. This team's role is to provide overall guidance and

direction for the design and implementation of the LCD process, and to help ensure the effort remains relevant to on-the-ground conservation and restoration actions. These partners are supported by a Core Team of staff of Sky Island Alliance (a local non-profit organization), the US Fish and Wildlife Service, and Southwest Decision Resources (facilitation and collaboration specialists). The Coordinating Team meets regularly to share information on partner activities, guide the development of collaborative tools, and plan workshops.

Collaborative Vision, Management Strategies, and Priority Ecosystems

After laying the foundational groundwork, the Madrean LCD effort was kicked off more broadly with Madrean Partner Workshop One in Tucson, Arizona in 2016. At this important gathering, more than 90 partners worked to develop shared goals and objectives, key management questions, and information gaps. Participants also identified locally relevant management strategies that are or can be used to help achieve shared goals.

An important outcome of this gathering was the shared development of the Madrean Watersheds Vision and Shared Goals for biodiversity, connectivity and socio-ecological services, each listed below:

Madrean Watersheds Vision

The Transboundary Madrean Watersheds initiative is a large-landscape, international effort to maintain and enhance the interconnected system of mountains, grasslands, deserts and waters that supports species diversity, promotes healthy watersheds, and maintains the overall ecosystem integrity that enriches the lives of human communities.

Shared Goals

Biodiversity: Transboundary Madrean watersheds are a haven for the unique diversity of native and endemic species.

Connectivity: Enhanced linkages connect the diverse life zones of Sky Island ecosystems, from valley bottoms to mountain tops, from southern Sonora to the Gila River in Arizona, enabling persistence of migratory wildlife and allowing for the possible future shift of species and ecosystems in a changing climate.

Socio-Ecological Services: Healthy watersheds, functioning ecosystems and cultural resources deliver highly valued benefits to human communities.

Additionally, workshop participants agreed on a list of priority ecosystems within the LCD geography, and they began work on developing appropriate indicators to assess landscape health and determine priority conservation actions in grasslands, Madrean evergreen woodlands, and streams. Biodiversity and connectivity were suggested as cross-ecosystems priorities.

Selection of Indicators of Landscape Health

In 2017, partners of the Madrean LCD began the important process of identifying key ecological and social indicators for the agreed upon priority ecosystems. The indicators will help assess both current and future ecosystem conditions, and provide a baseline and ongoing mechanism to detect changes that result from collaborative management actions. Madrean LCD partners developed criteria for these indicators, and met in February 2017 to evaluate a range of suggested options. Indicators selected were spatially based, ecologically and socially relevant, relevant to management and conservation goals of partner organizations, and able to guide the placement of conservation and restoration activities (*Madrean Landscape Conservation Design, 2018*, Madrean Watersheds Landscape Conservation Design: Developing Indicators and Analysis Methods to Assess Ecosystem Integrity at the Watershed, Core, and Corridor Scales). Since the preliminary list of indicators was developed, Madrean LCD partners have worked to determine whether appropriate data was available for those indicators, and then to locate and compile this information.

Formation of Topical Teams

Since priority ecosystems and preliminary indicators of landscape health were identified, sub-teams have been convened to gather resources related to those topics. A data team comprised of the Arizona Remote Sensing Center, Sky Island Alliance, and Coordinating Team members gathered data related to ecosystem indicators. Practitioners with interest and experience in Biodiversity and Connectivity met to develop geospatial products for supporting planning and decision making related to those topics. These teams communicate regularly with the Coordinating Team to ensure the relevance of data and tools.

Development of Tools and Products

The Madrean LCD partners are developing products to promote resilience of the ecoregion. These tools are being developed collaboratively, and are publicly accessible. Updating and improving these tools will be an ongoing priority for the Madrean LCD. The resources being developed include the following:

- A watershed and landscape-scale indicator assessment: A geospatial depiction of the indicators of landscape health selected by the Madrean LCD. This tool will be utilized to monitor trends over time, as well as to support geographic prioritization of conservation actions.

- A map of wildlife corridors in the Madrean Sky Islands: A combination of the work of multiple partners who have studied and ground-truthed corridors for different species, this map will show corridors important for the use of multiple species in the Sky Islands.
- An interactive list of management strategies specific to the region: An online index of what managers are doing to promote a resilient Sky Islands landscape, providing context and guidance for when and where those strategies can be effective.
- The Collaborative Conservation Adaptation Strategies Toolbox (CCAST): This interactive website provides case studies on management strategies prioritized for the Madrean Watersheds and other LCDs, along with resources to support implementing these strategies on a larger scale. The tool is fully functional online at: <https://www.arcgis.com/apps/Cascade/index.html?appid=01245fcb9dec43938996e18b53f0f14>.
- Support of sub-watershed-scale conservation collaboratives: The Madrean Watersheds supported the development of local efforts, including the Lower San Pedro Collaborative and the Santa Cruz Watershed Collaborative, which align partners in gathering resources and planning for the sustainability of those respective watersheds. The LCD intends to support more local collaboratives through designing and adapting products at scales applicable to local groups, as well as participating in an effort to connect watershed collaboratives in the state of Arizona.

Lessons Learned From the Madrean LCD

Overview

The partners of the Madrean LCD have learned and applied various lessons throughout the process. Although the lessons are too numerous to include in one article, some key insights that may be applicable to other collaborative conservation efforts are described below.

Establishing a Foundation

While many partners are eager to implement on-the-ground activities, establishing shared goals and priorities at the outset of a collaborative effort is critical. In the Madrean LCD, early meetings and workshops focused on listing and connecting existing work and developing shared priorities, rather than immediately developing products. Although applicable products have taken years to create, they are informed by specific, priority needs identified by program partners. Maintaining transparent and consistent communication between participants in the ever-changing efforts and priorities has been instrumental in the success of the collaborative, and Madrean LCD partners are aware of the importance of continuously listening to the needs of partners and adapting collaborative priorities accordingly. Building upon existing efforts to create relevant products requires time and thorough communication, but time is ultimately saved by avoiding duplication, and by identifying and integrating ongoing work in the region.

Maintaining Momentum at Multiple Scales

As a landscape-scale collaborative, a key question to answer is when to establish overarching goals and planning priorities versus conducting local, smaller-scale work. Madrean LCD partners have learned the importance of operating at multiple scales simultaneously to maintain momentum. The Madrean LCD connects and leverages the abilities of individual partner organizations conducting local work while establishing larger-scale priorities and values through the Coordinating Team and workshops. If on-the-ground work is not being used to illustrate the relevance of the collaborative, the development of more abstract concepts such as overarching goals and priority ecosystems can lose momentum. The foundational concept of structuring the collaborative to support concurrent work at multiple scales can be applied to any large-landscape conservation collaborative.

Diversifying Funding Sources

One lesson learned regarding funding of the Madrean LCD occurred when the founding initiative, the Desert Landscape Conservation Cooperative, was discontinued. In 2017, the US government announced that federal funding would be eliminated for Landscape Conservation Cooperatives, removing the main support for the Madrean LCD by the end of 2019. However, Madrean LCD partners considered the effort an important priority, and are working on creative solutions, specifically a shared funding structure in which multiple partners contribute funding and staff time to support coordination and other ongoing needs. Through the sudden loss of the primary funding source, the Madrean LCD partners have learned that a diverse support base not only reduces risk, but also encourages a sense of ownership and agency among partners of the collaborative.

Participating Across Borders

A major challenge for the Madrean LCD has been maintaining close partnerships across the international border. The LCD was originally intended to have equal participation from the United States and Mexico; the potential to strengthen

international relationships was a main reason for establishing this collaborative. However, the fact that strong relationships only existed between a few Mexican and American organizations has made it difficult to continue engaging partners from both nations, especially as staff changes occur. Also, there are few contiguous geospatial data sources that span both countries of the Sky Islands, so there are currently few landscape indicators that can be monitored and analyzed throughout the entire Madrean LCD region. In addition, in-person gatherings are challenging; the language barrier slows technical conversations that require translation, and it is difficult for government employees of both nations to obtain permission and funding to travel across international lines.

Although it has been difficult to keep partners from both nations in discussion, multiple conservation goals and challenges are common to Mexican and American communities that unify the effort. Given that the steps to build relationships across nations can be slow, the Madrean LCD has learned that making a concerted effort to include and empower all communities and organizations involved is a critical part of the collaborative process, and it is more beneficial to put effort into building and maintaining relationships than losing participants and having to re-engage them later in the process.

Institutionalizing Partner Engagement

One strategy for keeping relationships strong across jurisdictions of the Madrean LCD has been institutionalizing organizational participation. As staff of partner organizations have come and gone, it has been important for participating organizations to send a new representative—particularly in the case of government agencies, which generally experience more participant turnover than landowners or non-governmental organizations. Strategies for institutionalizing organizational participation include investing decision makers and land managers early in the process so that they understand its relevance and benefits; listing participant organizations in written documents of the collaborative to encourage a sense of belonging; and consistently gathering feedback from partner organizations to assure the tools and outcomes are directly useful.

What's Next for Collaborative Conservation in the Sky Islands?

Based on the work to date, lessons learned, and current partner needs, the Madrean LCD plans to continue as a fully functioning collaborative supported by multiple partner organizations that provide resources to local watershed collaboratives and scale up initiatives and priorities currently conducted at smaller scales. The Madrean LCD will host a workshop in 2019 to convene partners working on critical issues and identify collaborative projects for the short- and long-term. Madrean LCD partners will also apply the indicators of landscape health and the connectivity map to prioritize areas for conservation action. Madrean LCD partners have re-affirmed the importance of strengthening binational relationships, cultivating place-based connections and environmental stewardship, and integrating science and policy (Madrean Landscape Conservation Design, Synthesis of Partner Input 2018). Utilizing this approach, the Madrean LCD will continue as a robust partnership to promote collaborative efforts for ecosystem resilience in the years to come.

Abstract

The alpine biome is the life zone above the climatic treeline in mountains. It is the only biome that has a global distribution, although its elevation varies with latitude. The alpine is treeless by definition; its vegetation is composed of plants that grow close to the ground, including grasses, sedges, rushes, herbs, dwarf shrubs and cushion plants. The alpine biome covers about 3.3 million km² or 26% of the global mountain area. The alpine regions of the world support over 10,000 flowering plant species. This article provides an overview of the articles in the alpine section of the encyclopedia, including description and discussion of the alpine regions of North America, South America, Africa, Europe, Asia, and Oceania. The world's alpine ecosystems are extremely vulnerable to the current human-caused changes, including rising temperatures, livestock grazing, air pollution encroaching from urban centers, invasive species, declining levels of meltwater, and other anthropogenic disturbances is putting alpine biota under a great deal of stress. As with all the other biomes of the world, we need to be taking steps to ameliorate these disturbances, before it is too late.

Introduction

How is the alpine biome defined? As reviewed by Körner (this volume), the alpine biome is the life zone above the climatic treeline in mountains. It is the only biome that has a global distribution, although its elevation varies with latitude. The alpine is treeless by definition; its vegetation is composed of plants that grow close to the ground, including grasses, sedges, rushes, herbs, dwarf shrubs and cushion plants. Cryptogams (mosses, lichens, and liverworts) play an important role in some alpine regions. Generally, flowering plant diversity in the alpine is far greater than that of cryptogams, even though the latter group dominates the ground cover of some habitats. For instance, in the Himalaya alpine flowering plants comprise 87% of the flora (1585 species), while mosses, liverworts and lichens represent 13% (244 species).

The alpine biome covers about 3.3 million km² or 26% of the global mountain area. The alpine regions of the world support over 10,000 flowering plant species in 2000 genera, representing 100 families.

The productivity of alpine ecosystems is limited by the short duration of favorable daytime periods and a nutrient cycle slowed by frozen soils. The alpine biome is largely confined to the Holarctic region, with only tiny alpine land areas in Africa, Australia and Oceania. The alpine regions and the treeless Arctic lowlands, also covered by short stature plant communities, are often lumped under the term "tundra." However, Arctic tundra lacks the characteristic features of the alpine landscape. Alpine topography is rugged, creating high habitat diversity. Alpine ecosystems generally clothe steep terrain, Arctic tundra often grows on flat lands and hill country, and is often dominated by peatland (mires, fens), which are rare in mountains. Hence the term "tundra" is best not applied to the alpine biome, and the term "alpine tundra" has been avoided by the authors of this section of the encyclopedia.

Climatic Controls of High Elevation Treelines

Körner (this volume) also reviewed the climatic controls of the treeline elevations around the world. The worldwide position of treeline roughly corresponds with the 6 °C seasonal mean temperature isotherm. Below this temperature trees are unable to build new cells and tissues. In regions of extremely cold climate, such as the subpolar latitudes or at high mountain elevations, trees disappear from the landscape and only small plants can survive on the land above the limit of trees. Trees at high elevations are exposed to the lower temperatures and higher wind speeds found 2 m and more above the surface, while small plants profit from the warmth near the ground. At treeline, the windward side of trees is blasted by ice crystals through the winter, eventually creating a "flag tree"

Fig. 1 Engelmann spruce growing at treeline, Colorado Front Range. Note the lack of branches on the windward side of the tree. Englemann spruce at treeline Colorado, courtesy of Creative Commons.

with branches only on the leeward side of the tree (Fig. 1). Tree species that live in the forest-alpine ecotone also adopt a krummholz growth form, in which the plant is dwarfed, standing only a little taller than the surrounding herbaceous vegetation. The term “krummholz” is German for “twisted wood.” Above the forest-alpine boundary, tree islands may be found in some alpine regions (Fig. 2). These patches of krummholz are weather-driven specimens of deformed treeline species adrift in the alpine community

Fig. 2 Above: Diagram of a krummholz tree island, showing the effects of wind. Below: A tree island on Niwot Ridge, Front Range, Colorado. Above modified from Holtmeier, F. K. and Broll, G. (2017b). Feedback effects of clonal groups and tree clusters on site conditions at the treeline: Implications for treeline dynamics. *Climate Research* **73**, 85–96, photo courtesy of Tim Seastedt.

(Holtmeier and Broll, 2017b). This phenomenon is unique to conifers employing adventitious root growth. Tree islands are generally triangular in shape, with the point of the triangle hugging the ground as it faces into the wind, and the leeward base of the triangle reaching a meter or more in height. Tree islands are often up to five meters in length. They may start as detached segments of treeline individuals or have their genesis from seeds germinating in acceptable microclimates. Tree islands slowly migrate across alpine landscapes, always in the leeward direction. Growth takes place on the downwind side through the spread of adventitious roots. The roots take advantage of the snow-derived moisture that accumulates on the leeward side of the island, as well as alpine loess that collects in the eddy behind the island. Meanwhile, the upwind side of the island is slowly killed by the erosive effects of the wind. The migration rate of tree islands has been measured by radiocarbon dating of wood samples from the windward and leeward edges of islands in the Colorado alpine. The average migration rate was measured at 0.9–1.9 cm per year in this study (Benedict, 1984).

If global warming continues at its current pace, ecologists predict that mountain treelines will shift upslope, thus reducing the areal extent of alpine biomes.

Regional Studies

North America

As reviewed by Malanson (this volume), the alpine biome of North America is responding to a variety of ongoing anthropogenic environmental changes. These include changes in climate, nitrogen deposition, invasive species, and local human activity. The environmental factors that influence treeline elevations at the global, regional and landscape scale are discussed by Holtmeier and Broll (2017a) and are shown in Fig. 3. Terrestrial ecosystems are more affected by climate change and local human disturbances, while aquatic ecosystems are more greatly affected by nitrogen deposition and invasive species. Alpine vegetation varies over short distances and, because it is found in a wide variety of microclimates, responses to climate change may be habitat specific. Warmer climates speed up snowmelt in the alpine, lengthening the growing season by days or weeks. This might seem to be to the advantage of alpine plants, but these species have evolved in colder climatic regimes with short summers. Jump starting their period of summer activity leads to changes in the timing of biological events, or their *phenology*. For plants, these biological events include the timing of sprouting, flowering, setting seeds, and dying back for the winter. The relationships between flowering plants and pollinating insects in the alpine (as elsewhere) have been established through millennia of interactions. If a species of plant has traditionally blossomed between July 1 and 10, then the corresponding pollinators will show up on those dates. If, however, the timing of blossoming moves up by 10 days, then the insect pollinators will arrive too late. These kinds of relationships between alpine biota are likely to be greatly disturbed by warming climates.

High elevation vegetation response to climate change is also profoundly affected by snow persistence. Snow affects alpine plants through thermal protection, water provision, effect on atmospheric deposition, and determination of the length of the growing season. Higher temperatures are likely to reduce snow persistence. This will change the seasonality of alpine plants. Zhu et al. (2019) note that increasing temperatures in arctic and alpine regions will likely lead to fewer days of snowpack cover of landscapes. Many alpine plants and animals rely on winter snow cover to insulate them from bitterly cold air temperatures. The number of winter days without alpine snow cover in the mid-latitude highlands of the Northern Hemisphere are predicted to increase by 10 days per year in the next few decades. Thus, counterintuitively, warmer alpine winter temperatures will lead to increased exposure of sub-nivean organisms to bare ground in winter.

As discussed by Schoville and Rovito (this volume), North American alpine habitats harbor an exceptional number of plant species, as well as high levels of endemism in several distinct biomes. These include the cloud forest biome, subalpine biome and alpine biome found at high elevations in tropical and temperate mountains. The alpine zones of tropical North America (including Mexico) have more diverse floras and faunas than alpine regions in the mid- and high-latitudes. This trend is also seen in alpine mammalian faunal diversity. The Sierra Madre del Sur (16–19°N) is home to 245 species of mammals; the Sierra Madre Occidental (24–30°N) has 217 species of mammals; the Pacific Coast Range (38–58°N) has 208 mammal species. The least diverse mammal fauna is found in the Brooks Range of Arctic Alaska (67–69°N), with just 48 species of mammals. Similar latitudinal trends in species diversity hold true for alpine plants in North America.

What are the environmental factors that govern these patterns of diversity? As reviewed by Seastedt (this volume), at the landscape level, moisture and temperature regime are the dominant factors. At smaller spatial scales the biotic characteristics of plants come into play. Resource availability at the microhabitat level plays an important role in alpine species composition. Another factor that influences species diversity and composition in alpine regions is the environmental history of the mountains. South of the Arctic, alpine regions form habitat islands, surrounded by a “sea” of montane forests. During Pleistocene glaciations, treeline elevations descended by 1000 m or more, creating much larger alpine areas, albeit many of these highlands were covered by glaciers. During these intervals, alpine “islands” became “peninsulas,” allowing the migration of alpine species along these high mountain corridors (Fig. 4). The current flora and fauna of any alpine region are thus not stable communities over the long-term. Instead they represent the mixture of alpine species that became established during the last glaciation, when movements between alpine regions were greatly facilitated by the alpine connections that existed. Sadly, the North American alpine ecosystems that have waxed and waned through millennia may soon be exterminated. Climate models predict that the cold climate associated with the alpine biome will eventually cease to exist in the continental United States, given the current trends in climate change.

Fig. 3 Diagram illustrating the environmental factors (abiotic and biotic) that affect the altitudinal treeline at the global, regional and local landscape scales. Treeline elevation flow chart—heavily modified from Holtmeier, F. K. and Broll, G. (2017a). Treelines—Approaches at different scales. *Sustainability* 9: 808. <https://doi.org/10.3390/su9050808>.

South America

The alpine regions of South America are found along the tops of the Andes, the longest mountain chain in the world. Because the Andes span a huge range of latitudes, from 11°N in Colombia to 55°S in Chile, they support a wide variety of alpine habitats, ranging from sub-Antarctic alpine regions in southern Patagonia, through high-altitude alpine environments in the tropical latitudes to the north. As reviewed by Anthelme and Peyre (this volume), alpine biodiversity of the Andes is the richest in the world. It displays remarkable patterns of endemism, species radiations and morphological/physiological adaptations. Mountain building (orogeny) of the Andes began in the Early Jurassic and has continued to the present day. As the mountains slowly rose from the plains, new niches were formed that became available for colonization by both temperate and tropical species. These alpine ecosystems of the Andes are highly vulnerable to the combined effects of climate and land use changes. Extinction is already occurring at alarming rates in many plant groups. New threats, such as the introduction of invasive species and the creation of no-analog communities through new climatic regimes, will directly impact the biodiversity of the Andes alpine regions. The following regional summaries follow a north-south transect along the Andes.

Hofstede and LLambí examine the plant diversity in Páramo communities, found in the high mountains of the neotropical region. The páramo landscape consists of natural grasslands above treeline (3000–3500 m asl) and below glaciers

Fig. 4 Above: Map of the modern vegetation zones of Colorado, showing the isolated patches of alpine vegetation (*white*) surrounded by subalpine forests (*light green*). Below: Reconstruction of the extent of alpine tundra during the height of the last glacialiation, ca. 21,000 years ago. Note how most of the alpine regions have coalesced, allowing biotic interchange.

(4500–5000 m asl). This ecosystem covers $\sim 35,000 \text{ km}^2$ and extends across the tops of the Andes in Venezuela, Colombia, Ecuador, and northern Peru (Fig. 5). In addition, small patches of Páramo occur in Costa Rica and Panama. Thus, the Páramo forms an ecological archipelago, spread along the highest parts of the northern Andes. One of the characteristics of Páramo is that it is subjected to large daily temperature fluctuations. Mist cover alternates with high levels of solar radiation. Páramo plant species have developed unique adaptive strategies to cope with these extreme environments. These species show high levels of endemism. In fact, the Páramo has the highest alpine plant diversity in the world. A comparison of 19th century vegetation records with recent vegetation surveys of the Chimborazo volcano, Ecuador, suggest there has been an upward migration of many plant species associated with temperature warming. It is predicted by ecologists that ensuing climate change will cause the loss and fragmentation of

Fig. 5 Map of northwestern South America, showing locations of Páramo vegetation (in red) and the northern part of the Puna region (in green). Modified from Kappelle, M. and Horn, S. P. (2017). The Páramo ecosystem of Costa Rica's highlands. In: Kappelle, M. (ed.), *Costa Rican ecosystems*, pp. 492–523. Chicago: University of Chicago Press.

páramo habitat, exacerbating the risk of extinction of alpine species. However, more long-term, comparative field monitoring is essential to document the effects of climate change on high elevation páramo plant communities.

The Puna biome includes three subregions: High Andean Puna, Wet Puna, and wet montane grassland, as described by [Worldwildlife.org](https://www.worldwildlife.org/species-and-ecosystems/puna) (2019a,b). The High Andean Puna is found from 4200 to 5000 m asl. The area has highly contrasting diurnal temperatures, with summer warmth during the day and winter cold at night. As in the Páramo, the extreme daily temperature oscillations have been a selective force in the adaptation of plants to this environment. The Puna vegetation faces nightly freezes throughout the year. The annual precipitation at high elevations is < 700 mm, falling as snow and hail.

The Wet Puna is located on the Altiplano, from 3700 to 4200 m asl. The Wet Puna ecoregion is predominantly a high elevation grassland, ranging along the alpine regions of most of Peru to northern Bolivia. Treeline in the Wet Puna region lies at 3500 m asl. The regional vegetation includes bunchgrass communities, wetlands, small shrubs and trees, and herbaceous plants.

The precipitation regime in the Altiplano falls along a north-south divide. Northern regions (surrounding Lake Titicaca) have eight wet months, whereas southern regions have only one to two wet months per year. The wet montane grasslands are found in the eastern part of the Puna, from 3800 to 4200 m asl. Many endemic plant genera have centers of diversity in the Wet Puna, including *Culcitium*, *Perezia*, and *Polylepis*. Other endemic genera include *Alpaminia*, *Weberbaueria*, and *Mniodes*.

The Dry Puna ecoregion is found in parts of Argentina, Bolivia and Chile. The region lies 3500–5000 m asl. Like the Wet Puna, the Dry Puna experiences highly contrasting diurnal temperatures. The northern part of the ecoregion has temperatures ranging from 8 °C to 11 °C, and temperatures in the southern area are even lower. Annual precipitation in the Dry Puna is extremely variable, ranging from 51 to 406 mm.

At elevations over 4000 m asl, the vegetation is dominated by cushion bogs includes floating submerged cushion plants. Large cushions are formed by *Distichia muscoides*, *Oxychloe andina* and *Plantago rigida*. Other genera include *Gentiana*, *Hypsela*, *Isoetes*, *Lilaeopsis*, *Ourisia*, and *Scirpus*. Well-drained areas are home to other cushion plants, such as *Azorella compacta* (Fig. 6) and *Werneria aretioides*. The vegetation changes from east to west in the Dry Puna, from shrubland steppe with dry-adapted shrubs such as *Adesmia* (Fig. 6) *Nassauvia lagascae* (Fig. 6), *Baccharis*, *Fabiana*, and *Senecio* to grassy steppe with *Calamagrostis*, *Festuca*, and *Stipa*. The western slopes of the Andes in this region are extremely arid, forming the Atacama Desert, where the average annual precipitation is 15 mm, and in some years, there is no precipitation.

The entire Andean Puna has been greatly impacted by centuries of livestock grazing, burning, firewood collection and clearance for cultivation. Camelids, goats and sheep degrade the herbaceous vegetation, interfering with parts of their life cycles.

Ezcurra and Gavini review the alpine plant diversity of the mountains in the temperate latitudes of South America. The alpine ecosystems of this region fall south of the Puna region (Fig. 7) and extend to the tip of South America. The dry temperate Andes

(30°–37°S) reach elevations > 5000 m and are arid or semiarid. The alpine zone in this region lies above 3000 m and is bounded by xeric woods, matorral, and steppe. Further south, the wet temperate Andes (37°–55°S) are not as tall (< 3000 m elevation) but receive more precipitation. These alpine areas are surrounded by *Nothofagus* forest or krummholz. As in other parts of the world, treeline descends with latitude. It occurs about 2000 m above sea level (asl) in the north, ranging down to about 500 m in the south. The species diversity of vegetation in the temperate Andes is greatest at intermediate elevations, with decreasing species richness both towards treeline and toward mountain tops. Ezcurra and Gavini attribute the higher levels of plant diversity at middle elevations mainly to the positive effects of plant-plant interactions, especially the nursing of seedlings of various plant species by surrounding cushion plants. While this phenomenon is not unique to this region, it plays a vital role here because the harsh diurnal temperature and moisture fluctuations restrict seedling establishment, unless the seedlings sprout in the buffered environment provided by cushion plants.

The arid Patagonian region of Argentina is an important area for conservation due to the high levels of endemism. However, the natural vegetation cover of this region has been highly degraded as a result of human activities. Ecological rehabilitation strategies have been implemented to recover certain areas. One effort to restore native grasslands was a multi-year replanting of native species, including a perennial grass, *Pappostipa humilis* (Fig. 6). This, and another species (*P. speciosa*) were tested as possible “nurse species” that might help nurture seedlings of other native plants, in order to restore as much of the natural vegetation as possible (González and Pérez, 2017).

The mammal fauna of the Andes, as described by Novillo et al. (this volume), includes 200 species from 10 orders and 27 families. The greatest species richness is concentrated in two different areas: the ecotone between the Puna and the Yungas Montane forest, and the southern Páramo. The mammal fauna of the Andes consists of a combination of endemic alpine taxa, species whose main distribution is in the alpine, and species that are more broadly distributed, and only marginally reach high elevations. Rodent species represent almost 70% of all Andean mammals, followed by bats and carnivores, which account for 8% and 5% respectively. Andean mammals face several conservation threats, associated mainly with habitat loss or transformation, climate change and invasive species introduction. Among Andean species, near 20% have some degree of conservation concern, while 15% are considered data deficient.

Sevillano-Ríos et al. (this volume) review the environmental threats facing the bird species inhabiting the High Andes (> 2500 m asl). Altogether, the High Andes habitats host 945 species, composed of both resident and migratory species, generalists, and highly specialized, endemic birds. This level of bird faunal diversity is almost as great as that of the entire United States. Many are specialized, mountain-top species, adapted to live within narrow elevational ranges and climatic conditions. This climatic limitation makes them particularly vulnerable to climate change. Many endemic mountaintop species could become extirpated (locally extinct) or die out completely because of global change. The decoupling of species-habitat and other ecological relationships that could arise from shifting vegetation zones may be particularly serious for highly specialized birds of the Páramo, *Polylepis* forests, and wetlands.

Africa

Most high-elevation African mountains are isolated peaks or small groups of high mountains, separated into discrete island-like archipelagos. Many of these high elevation regions are remote, difficult to access, and thus far poorly studied.

Brown and du Preez (this volume) review the alpine vegetation of the temperate latitudes in Africa. The cluster of mountains in East Africa and the Chimanimani Mountains in Zimbabwe are separated by the broad Zambezi valley, and the latter is separated from the South African cluster by the Limpopo valley. The vegetation of the high African mountains consists of various elevational belts. The upper most belt (>3600 m asl), absent in southern Africa, is the Afroalpine ecoregion, with vegetation cover of bryophytes, tussock grasses, giant lobelias (*Lobelia* spp.) and senecios (*Dendrosenecio* spp.) (Fig. 8). A sub-Alpine belt (between 2800 and 3600 m) is characterized by sclerophyllous genera such as *Erica*, *Philippia*, *Cliffortia*, and *Passerina*. These plants have leaves that are evergreen, hard, thick, leathery, and usually small. These adaptations conserve water in the plant. Lower down an undifferentiated Afromontane vegetation belt (1800–2800 m) consists of indigenous forests, shrublands, moist grasslands and wetlands.

Carbutt (this volume) points out that the Afroalpine region is a center of plant endemism. About 81% of its plant species and four plant genera are unique to this region. But unlike the highly endemic flora of the Andes, the Afroalpine flora is species-poor with about 300–680 vascular plant species known from the various mountains. The most iconic plants of the Afroalpine region are the giant *Lobelia* and *Dendrosenecio*. These are well adapted to the strong diurnal-nocturnal temperature ranges experienced throughout the year. Some alpine shrub species thrive on the thin soils between rocky outcrops. *Protea kilimandscharica* (Fig. 8)

is found in this habitat, as described from Mount Kenya. The dwarf shrub *Helichrysum newii* (Fig. 8) thrives above treeline on Mount Kilimanjaro, especially near the rim of the ancient volcano.

The ecology of the Afroalpine ecoregions near the equator is reviewed by de Deus Vidal and Clark (this volume). This zone is isolated on mountaintops over 3200 m asl, and is found on 14 scattered mountains, covering 4525 km². This alpine region harbors between 515 and 521 species of flowering plants, 52 fern species, and >277 moss species. Endemism levels are around 35% for flowering plants and are 30% for mosses. Typical plant communities include tussock- and shrub-dominated grasslands and alpine bogs or fens, in which are embedded communities of Giant Lobelias and particularly Giant Groundsels (*Dendrosenecio*). Due to the difficulty of exploration in some of these mountains and the limitation of the available literature, this ecosystem needs more systematic research.

Töpfer and Gedeon (this volume) give an account of the alpine bird fauna of Africa. The Afroalpine bird fauna is small, particularly in relation to the Afromontane regions downslope from the alpine, where species diversity is far greater. In fact, there are no bird species unique to the Afroalpine. Rather, the alpine birds are a small subset of the Afromontane community. The Afroalpine bird fauna is comprised of four groups: (1) obligate biome-confined breeding residents (Ruddy Shelduck, Golden Eagle, and Red-billed Cough), (2) regular biome-affiliated residents (Thekla Lark, Brown Warbler, and Ankoher Serin), (3) facultative biome-affiliated residents (six species of tropical birds), (4) opportunistic residents and visitors (36 species of a variety of lowland habitats). To an even greater extent than with Afroalpine botanical studies, Afroalpine ornithology has only recently begun to assess the bird fauna of these habitat islands. Especially on a smaller geographic scale, information on regional or local differences between alpine bird communities remains fragmentary. Only 47 bird taxa are more-or-less confined to the Afroalpine.

Of the 25 nonpasserine bird taxa found in the Afroalpine, 17 are raptors, including owls. Of the 22 passerine taxa, five are seed-eaters that belong to just two genera (*Serinus* and *Crithagra*). Some of these birds deserve a closer look by ecologists, as they play important roles in the Afroalpine, even though they might not be found there exclusively.

The Afroalpine mammal fauna has been reviewed by Pillay and Joshi (this volume). Their definition of the Afroalpine zone is much broader than the other authors in this volume, as they consider the Afroalpine zone to be areas above 1800 m asl. Within this broader range of habitats, there are 109 mammal species in 10 orders. Endemic species account for 60% of the fauna and 38% are currently of conservation concern. As elsewhere, rodents constitute the majority of these mammals (53%). These small mammals display a variety of adaptations that reduce their exposure to lethal temperatures. As with bird studies, Afroalpine mammals are poorly studied in many of the representative countries because of their inaccessibility, the small number of field biologists and a lack of consistent field surveys.

Small mammals in the Afroalpine must cope with below freezing nighttime temperatures, year-round. Several rodents show behavioral, morphological and physiological adaptations to cold. For instance, to avoid lethal temperatures in the Bale mountains, some rodents are diurnal, rather than the typical nocturnal behavior pattern. This diurnal activity pattern is found in five species of Afroalpine rats. Some seek shelter in shrubs and rocky outcrops, which provide some protection from the freezing temperatures of the open valley habitats where they forage. Temperatures below ground remain more or less constant at a soil depth of 50 cm and even in shallower burrows. Thus, many small Afroalpine mammals avoid cold temperatures by nesting belowground.

Climate warming will likely cause Afro-alpine endemics to become very restricted in an already confined environment, with some species—especially those most obvious flagship giants adapted to the diurnal freeze-thaw cycle—being most at extinction risk. In addition, many high-elevation ecosystems in Africa are threatened by anthropogenic influences, of which overgrazing by domesticated animals tops the list. It is expected that because of their low competitive ability, alpine species will decrease in number while species from the lower-lying areas, better adapted to warmer conditions, will increase in number. Other human-caused threats include various land use changes such as massive deforestation and heavy agricultural intensification. These disturbances are already directly affecting even the fragile upper habitats of African mountains. A total of 38% of Afroalpine mammals are currently endangered, a number that is likely to increase in future. These mammals face a range of threats, most notably habitat destruction through human expansion and activity and ultimately global climate change.

Asia

The Asian mountain system consists of a series of mountain ranges and plateaus around Tibet (including the Pamir, Kunlun and Tien Shan Mountains). Mountains and highlands with alpine life zones extend to southern Asia along the Hindu Kush, Karakoram, Himalaya, and isolated peaks in Borneo, Sumatra, Lombok and New Guinea. Western Asian mountain ranges include the Urals, mountain ranges around the Iran Plateau, the Trans-Caucasian and Pontic Mountains, and some peaks on the Arabian Peninsula. In northern Asia, alpine ecoregions occur in the Altai, Sayan, Changai, East Siberian and Kamchatkan mountains with the transition from alpine to arctic habitats, as well as some ranges Eastern and Southern China, Taiwan, Korea, and Japan (Schickhoff and Mal, this volume).

Negi and Mukherjee (this volume) review the climate change impacts in the Himalayan mountain ecosystems. They note the significant absence of long-term climate observations and ecological data collection throughout the Himalayas, particularly in the alpine regions. The average annual temperature over the Asian land mass, including the Himalayas, is predicted to increase by about 3 °C by the 2050s and about 5 °C by the 2080s (IPCC, 2007), and average annual precipitation will increase by 10–30% by the 2080s (IPCC, 2007). Satellite imagery suggests that the margins of almost two-thirds of the glaciers in the Himalaya have retreated in recent decades. For example, in Central Himalayan region of Nepal, glacial margins are retreating by as much as 10 m/year (Fig. 9). According to the International Commission for Snow and Ice, glaciers in the Himalayas are receding faster

Fig. 9 Photo of the eastern terminus of Imja Lake where it meets Imja Glacier, Nepal, by Daniel Alton Byers, Creative Commons. The margins of this glacier are retreating by as much as 10 m/year. Photo of Imja Glacier, Nepal by Daniel Alton Byers, Creative Commons.

than in any other part of the world. If the present rate continues, they will probably disappear by 2035. Snow cover is another critical environmental aspect of Asian highlands. The snow-covered area of Asian mountains has significantly declined, especially since the 1960s. Snow-cover duration in the greater Himalayan region has decreased by 30 days per year in recent decades.

The alpine plant diversity of the temperate mountains of Asia is described by Sridith (this volume). Their article focuses on the alpine regions of the Himalayas and the Tibetan Plateau. This vegetation is characterized by dwarf shrubs with rhododendron growing in krummholz form at the forest-tundra ecotone. Alpine grassland is also rather common from the tree line up to the snow line. There is a high diversity of herbaceous vascular plants including some selected grasses and sedges, and this vegetation is more-or-less protected from livestock grazing because of steep slopes (angles over 45°) (Baniya, 2010). However, even the vegetation on the steepest slopes is not immune to the effects of climate change. The melting of glaciers is leading to changes in surface and groundwater hydrology of the Himalayas. This, in turn, is causing habitat and species loss.

As discussed by Schickhoff and Mal (this volume), climate change in the Himalayas is causing upslope expansion of subalpine species, changes in treeline dynamics, phenological shifts, and changes in primary production. The introduction of invasive species is increasing and is facilitated by warming climates.

The alpine regions of tropical Asia are confined to high mountaintops on islands. The New Guinea alpine zone, as discussed by Hope (this volume) lies above 3750 m asl. This is the highest, largest and wettest such region on any tropical island. The modern alpine consists of habitat islands spread over 1400 km with considerable variations in biodiversity between the individual mountain areas. The use of fire by native peoples has expanded open areas of vegetation near treeline over the past several thousand years. The alpine is threatened by increased warming and potential invasion by emergent shrubs but is unlikely to disappear, provided that wet conditions continue to prevail. With few exceptions, land management depends on local populations; widespread fires during El Niño-induced dry phases point to continuing human impacts linked to drought events.

New Zealand and Polynesia

As discussed by Lord (this volume), New Zealand harbors the most significant alpine ecosystems in the Southern Hemisphere outside of South America. Because of its long-term isolation, the alpine biota of New Zealand has high levels of endemism. Treeline in New Zealand varies from 1400 m asl in central North Island (39°S) to 900 m in south-western South Island (46°S). The elevational tree limit in New Zealand is dominated by evergreen *Nothofagus* trees. New Zealand's alpine areas are geologically recent and tectonically highly active, which has led to allopatric speciation and many poorly understood species complexes among plants, invertebrates and reptiles. In the alpine region, over 90% of plants are endemic. New Zealand's alpine biota has had to adapt to climatic unpredictability. This adaptability may buffer the effects of future climate change on New Zealand's alpine biota. The greatest threats to New Zealand alpine ecosystems are invasion by introduced pest species, most notably cold tolerant conifers, ungulates and rodents. In much of South Island, low diversity southern beech forest gives way abruptly to a low alpine zone of tall grassland dominated by the near endemic tussock genus *Chionochloa*. In central South Island, the alpine vegetation also consists of tall tussock grassland. The dominance of tall tussock-forming grasses and large-leaved, evergreen herbaceous plants in New Zealand's low alpine ecosystems differentiate them from temperate alpine areas of the Northern Hemisphere. Instead, these ecosystems more closely

resemble alpine ecosystems of tropical high mountains such as those of Africa that experience extreme temperature variations during diurnal cycles year-round.

The climate of the alpine zone in New Zealand and Hawaii is cold, and precipitation levels are highly variable. Mean annual alpine temperatures range from -6.9°C to 8.2°C in New Zealand and from 3.6°C to 10°C in Hawaii. New Zealand is subject to westerly winds in the mid-latitudes, while Hawaii is subject to the northeast trade winds in the tropics. The perpendicular orientation of the mountains to the prevailing moisture-laden winds results in extremely wet windward areas, amounting to over 10,000 mm per year on both the western slopes in New Zealand and the eastern slopes in Hawaii. In stark contrast to the wet windward regions, the dry leeward regions lie in rain shadows where precipitation can be as little as 500 mm per year in New Zealand and 200 mm per year in Hawaii.

Alpine ecosystems in the Pacific Islands are isolated and are also characterized by high levels of endemism, as discussed by Frazier and Brewington (this volume). Only Hawaii and New Zealand have mountains sufficiently tall to contain substantial alpine environments. In the alpine and subalpine ecosystems of Hawaii, 84% of plant species are endemic. About 11% of the land area of both island groups is located above treeline. The treeline of Mauna Kea is located about 2900 m asl. The treelines of Mauna Loa and Haleakalā are at least 450 m lower than on Mauna Kea, which may be due to soil-dependent factors. On the northeastern slope of Haleakalā, treeline occurs around 2100 m asl. Treeline elevation varies elsewhere in Hawaii. In most localities, native subalpine cloud forest gives way to alpine shrublands, herbs, and tussock grasslands that form a fog-drip community. Alpine desert conditions exist on Maui and Hawaii Island above about 3000 m asl.

These alpine ecosystems are threatened by invasion of exotic species, climate change, and human impacts. Both New Zealand and Hawaii have experienced strong warming at higher elevations, and future projections indicate that these warming trends will continue. For Hawaii, future projections of temperature indicate that the greatest warming will occur at the highest elevations. Projections range from 3.5°C to 5°C warmer temperatures by 2100. Glacial retreat has been noted in the Southern Alps of New Zealand, with 34% ice volume lost since 1977, and climate models predict that New Zealand as a whole may lose 88% of its ice volume by 2100. Similarly, snowfall on Hawaii's mountain peaks is projected to almost entirely disappear by 2100.

Current Human Impacts on Alpine Ecosystems

As we have seen, alpine ecosystems account for only a small percentage of terrestrial habitats yet, along with adjacent mountain systems, they provide water resources to nearly half of the world's human population. Approximately 20% of humans live in or near mountain areas, making it inherently important to understand current impacts on these systems. Cryosphere changes in the alpine include the melting of permanently frozen ground (permafrost), decline in snow cover duration and area, rapid retreat of glacial margins and thinning and water loss in alpine glaciers, with a total loss of 18% of glacier area occurring across > 900 alpine glaciers between 1985 and 1999 alone. Regional climate models project increases in alpine temperatures, combined with decreases in winter precipitation falling as snow and an increase in winter precipitation falling as rain. These coupled changes in temperature

Fig. 10 Photo of cattle grazing an alpine meadow in Switzerland. Photo of cattle grazing in Alps. Creative commons.

and precipitation will influence snow cover persistence and the timing of snowmelt which, in turn, will impact growing season length, productivity, and biogeochemical cycling in alpine systems worldwide. Most climate models predict an advance in the timing of alpine flowering in response to an advance in snowmelt timing. Alpine plant community composition has also shifted in recent decades, likely in response to warming. More than one-third of 125 plant species in the Alps have migrated at least 100 m higher than their historical lower elevation limits in recent decades, with simultaneous increases in abundance at their upper elevation limit that now experiences warmer temperatures. However, alpine plant response to increasing temperatures is often more complex than this. Many of the responses observed or predicted in alpine systems will be the result of complex, oftentimes interactive, processes. As discussed by Walsh and Gigu  t-Covex (this volume), the history of human disturbance of alpine landscapes in Europe extends back to 7000 years ago in the Neolithic Period. Livestock grazing has changed the species composition of Alpine vegetation over several millennia (Fig. 10).

In New Zealand and the Pacific islands, climate change, human-driven environmental degradation, and land use change have facilitated species invasions, to which these isolated alpine ecosystems are particularly vulnerable. The first known mammalian predator to arrive in New Zealand and Hawaii was the Polynesian rat around 800 years ago, but the vast majority of pests accompanied the European settlement of New Zealand and Hawaii in the 1800s, feral populations of red deer and rabbits have exerted significant pressure on New Zealand's alpine grasslands, while grazing livestock, especially sheep, also influence vegetation cover and species composition. Grazing livestock, including pigs, cattle, and goats, have severely affected Hawaiian alpine ecosystems, particularly in grassland-dominated areas. This has coincided with soil erosion and non-native plant invasions that have further reduced alpine plant community regeneration. Both New Zealand and Hawaii are far removed from mainland regions, so invasive species have been brought, either accidentally or deliberately. Hawaii has been called the poster child for invasive species. The Bishop Museum in Hawaii estimates that >5000 species of plants and animals occur in the Hawaiian Islands, including >1300 introduced vascular plant species.

Conclusions

The collection of articles on alpine ecosystems provides an excellent overview for each region. It is striking that these articles have so many themes in common. One would think that the nature of alpine regions in high-latitude North America or Asia would have little in common with the nature of alpine regions at the top of tropical islands, but this is not the case. Virtually all the alpine regions reviewed in the Alpine section of this encyclopedia share some common characteristics:

- (1) Most alpine regions represent habitat islands, isolated from each other by intervening valley systems that are impassable barriers to migration of many alpine taxa. This isolation makes alpine biota vulnerable to extinction in the face of severe environmental change, because recruitment of alpine biota from other habitat islands can only happen during glacial intervals.
- (2) There is a relatively high level of endemism in the flora and fauna. If enough populations of endemic species are driven to extinction, the whole species will die out, as there are no other regions from which new populations can be recruited.
- (3) Most of the fauna and flora of alpine regions are highly adapted to the severe physical environments in which they live. Because of this high level of adaptation, they are bound to suffer extirpations and extinctions when the climate becomes too warm. They already live on mountain tops, so there is no higher ground on which to seek cooler temperatures.
- (4) Global warming is amplified in many alpine regions of the world, exacerbating the pace and intensity of environmental change. This warming affects alpine communities in many ways, including changes in phenology of individual species, disturbance of species interactions, and invasion of more warm-adapted species from lower elevations.
- (5) Glaciers are decreasing in volume and their margins are retreating in most high mountain regions. Snow cover is shallower and is persisting fewer days per year. These changes are of such great magnitude that alpine glaciers may disappear within the next century. The decline of mountain snow and ice is causing hydrological changes that begin in the alpine zone (where soils can become desiccated) and continue downslope to the ocean. Melt water from alpine glaciers and snow fields is currently used for drinking, irrigation and hydroelectric power for about 1.5 billion people.
- (6) Many cultures around the world have tried to graze animals on the herbaceous vegetation of the high country. This invariably causes alpine habitat disturbance or destruction. Livestock grazing also facilitates the establishment of invasive species in the alpine, as it weakens the natural vegetation communities.

The take-home message here is that the world's alpine ecosystems are extremely tough when it comes to withstanding long, cold winters, but extremely vulnerable to the current human-caused changes because they have never before been exposed to them. The combination of rising temperatures, livestock grazing, air pollution encroaching from urban centers, invasive species, declining levels of meltwater, and other anthropogenic disturbances is putting alpine biota under a great deal of stress. As with all the other biomes of the world, we need to be taking steps to ameliorate these disturbances, before it is too late.

Abstract

The productivity and diversity of alpine ecosystems are two subjects that have attracted the attention of researchers for decades, but these characteristics have often been studied separately and at different spatial and temporal scales. Here, the relationships and causal mechanisms that appear to relate these two very different properties of ecosystems are presented. Recent studies confirm that at landscape-level scales controls are governed by moisture and energy, while at the smaller spatial scales the biotic characteristics that interact with resource availability are seen as important. These controls are now being influenced by directional environmental change drivers that will alter spatial relationships of alpine biota with other ecosystems and will both increase and decrease productivity and diversity within and among alpine areas.

Introduction

The alpine is renowned for its topography, biotic exuberances in summer, and extreme cold and wind in winter. The latter two features have perhaps been its salvation. While alpine regions can be found adjacent to large human populations, humans have not been able to dominate and transform these natural areas as has occurred in many other terrestrial ecosystems, at least not until recently. The isolation and topographic features of these islands in the sky have led to the evolution of biotic communities that are locally diverse and sculpted by multiple resource limitations. The time since the establishment of these communities varies from “just emerged from the Pleistocene ice” to sites that have been unglaciated for millennia and have a long evolutionary history of biotic interactions. The site heterogeneity and variation in time since establishment that characterize alpine areas are accompanied by a litany of stressors, including its short growing season, high levels of ultraviolet radiation, low soil fertility, and frequent freeze-thaw events that can occur during the growing season. Collectively these have resulted in the evolution of plant species possessing remarkable adaptations to these stressors (Körner, 2003). However, these communities must now experience climatic conditions and atmospheric chemistry drivers that have not been experienced since pre-Pleistocene times, if at all. This article summarizes recent findings that have attempted to clarify, elucidate, and advance new knowledge of these charismatic ecosystems and their adaptabilities and vulnerabilities in the emerging Anthropocene.

Is Alpine Tundra the Same as Arctic Tundra?

High elevation areas are often studied alongside high latitude areas. Both systems were identified and combined into a single study unit during the emergence of “big science,” the International Biological Program, during the 1960s (Worthington, 1975). Summaries and descriptions of these two similar-but-different systems are often combined in books (e.g., Chapin, 1995; Wielgolaski, 1975) and in volumes that discuss ‘the tundra biome’ as well as in journals (e.g., Arctic, Antarctic, and Alpine Research). A small to moderate percentage of plant species are shared between these two biomes (c.f., Billings, 1973; Cooper, 1989), and the low average temperatures and short growing seasons of both regions have affected vegetation structure and life-forms in similar ways. Both systems exhibit large variations in community types ranging from rock-covered lichens through wetland bogs, resulting in multiple combinations of vascular and nonvascular plant communities. The one common denominator is the lack of trees (or the presence of tree species with prostrate shrub growth-forms). Alpine ecosystems also evolved independently in tropical regions, and the major differences between arctic and alpine systems include the higher diurnal variation in temperature and irradiance experienced in the

alpine (Hedberg, 1997) and the relative importance of topography in controlling factors such as soil moisture and growing season length (Billings, 1973).

Alpine Plant Communities

Alpine ecosystems are composed of herbaceous plant communities found at elevations where soils are generally too cold to allow for forest growth (Körner and Paulsen, 2004). These communities are usually dominated by graminoid (= grasses + sedges + rushes) or forb (= nonwoody dicots) landscapes, although some woody species such as dwarf trees (krummholz), willows and other shrubs may also occur. Factors controlling the lower elevational limits of these meadows are a combination of temperature, moisture, wind, domestic grazing, and disturbances such as avalanches (Malanson et al., 2007; Bourgeron et al., 2015).

Alpine regions have held our interest in part because of their visual appeal, a factor related in part to the fact that flowering species often appear to dominate the landscape, and these alpine environments are often renowned for their floral displays. The forbs generally play a more dominant role in plant community structure than in other nonwoody communities such as grasslands and savannas. The abundance of forbs results in some alpine areas being referred to as “herbfields” (Chambers, 1995), however, dominance by forbs is often limited to small areas, and grasses and sedges usually dominate the dry, mesic, and wet meadows of alpine landscapes (Billings and Mooney, 1968). Still, the abundance of forbs in some alpine areas argues that mechanisms that contribute to the dominance of graminoid species in warmer climates not dominated by woody species are less effective in the alpine. Understanding these mechanisms remains a research focus.

Measuring Plant Diversity and Productivity in the Alpine

Plant diversity studies rely on the ability to identify species from a potentially large regional pool of vascular plants. To obtain statistical measures of species abundances, a sample area and sample size must be chosen. The standard sample unit can range from a fraction of a square meter to well over 100 m², with smaller plot areas usually selected in order to quantify differences due to community type or resulting from experimental manipulations. The point-intercept procedure (Fig. 1) is perhaps the most commonly used method to quantify alpine plant species and community characteristics. Point-intercept data can be used to estimate species number per plot (richness), amount of cover per species per plot, relative plant cover. These data can also be used to calculate species evenness and species diversity, which along with richness are the standard units of plant community ecology. Differences in plot size and in the way that various investigators have measured or calculated these variables limits the ability to conduct absolute comparisons among studies. However, the patterns and trends resulting from these measurements made across landscapes or experimental manipulations can be summarized.

Fig. 1 Plot plant species richness is often determined with point-intercept techniques, shown here, which can quantify the number of species as well as the amount of cover of alpine tundra plant species in small plots. A NEON (National Ecological Observatory Network) tower designed to measure carbon exchange and used to calculate GPP (gross primary productivity) for a large swath of tundra is seen in the background. Photo of Niwot Ridge, Colorado, taken by author.

Measurement of net plant production (NPP) requires measurements of the fates of the products of photosynthesis, both aboveground (ANPP) and belowground (BNPP). Historically, ANPP in the alpine was measured by clipping all aboveground live biomass down to the soil surface. Comparisons of these amounts were then made across various resource gradients, community types or treatments such as grazing or fertilizer additions (Bowman and Fisk, 2001). This technique assumes a strong correlation between the sample, usually harvested to represent peak biomass, and actual aboveground net primary production. In reality the estimate is affected by losses of biomass prior to collection or the failure to include additional production following the harvest. Losses due to aboveground herbivores and pathogens are often not included or assumed to be negligible. This low-tech method has been superseded by more sophisticated techniques, but the information gained relative to time and effort usually justifies the method.

Belowground estimates of plant materials produced per year are difficult to measure for multiple reasons, including the fact that live roots are often difficult to separate from dead roots that were produced in a previous year. Further, plants can produce large amounts of root exudates (Huo et al., 2017), allocate biomass produced by photosynthesis to mycorrhizal fungi (Marschner, 2012) as well as contribute a fraction of growth to root herbivores (Seastedt and Murray, 2008). Those contributions of NPP are rarely known or measured. While most aboveground growth of herbaceous species turns over (senesces) every year, a fraction of roots are longer-lived, meaning that belowground harvests do not represent annual production. Instead, root growth has been approximated by root ingrowth techniques (Fisk et al., 1998) or isotopic measurements (Smit et al., 2013), both of which are difficult to perform and time consuming.

Körner (2003) identified an important caveat about measurements of primary productivity in the alpine. A portion of what is included in an estimate of ANPP is allocation from stored materials accumulated in one or more previous years. Since alpine vegetation is dominated by perennial species, this contribution is potentially larger than in other herbaceous communities containing more annual species. This contribution, in addition to transfers to herbivores, and belowground transfers to root exudation and mycorrhizae mean that using biomass as a proxy for ANPP or NPP is problematic and arguably could be an over- or underestimate in any year. One might assume that underestimation is the rule (due primarily to losses to exudates and mycorrhizae), but in at least some years overestimates are possible.

More recently, a potentially much more precise, albeit large spatial scale estimate of gross primary production (GPP, the total amount of carbon fixed by plants per unit area per year prior to subtracting plant respiration costs) has been made possible through the use of carbon flux towers (e.g., Knowles et al., 2015; Fig. 1). These towers measure near-instantaneous changes in the downward and upward movements of carbon dioxide and, in doing so, can estimate net removal of carbon from the atmosphere into the plants during the growing season, and losses of carbon to respiration from all sources during periods when photosynthesis does not occur. Net primary production, in turn can be estimated as a fraction of GPP. Carbon flux towers are expensive to install and run, and the areas as well as the accuracy of measurements can be influenced by topography. As such, flux towers in alpine areas are few. However, given the large microsite heterogeneity in soils and plant resources found in the alpine (c.f., Körner, 2003), estimates from small sample areas come with very large variances and uncertainty of averages remains large without a major sampling effort. Both methods remain useful for addressing various questions, but the flux towers ultimately should provide the required knowledge of carbon flux and carbon sequestration in the alpine.

Patterns of Plant Diversity and Richness in Alpine Habitats

Alpine ecosystems occur in both the southern and northern hemispheres. Both are under fairly similar climatic constraints, but the separate evolutionary paths of different floras and faunas have generated some spectacular differences in alpine community composition. With the exception of a few plants (termed “bipolar arctic-alpine” by Billings and Mooney, 1968), these systems are biotically distinct. While the mechanisms that explain patterns in plant productivity and local diversity are suggested to hold for both hemispheres, one should expect some unique patterns generated by biotic communities that have evolved under unique resource and climatic constraints.

Factors affecting the numbers of species and their relative abundances within alpine areas have been a topic of interest for decades (Grabherr et al., 1995). Plant richness is often correlated with the long-term history and size of the local to regional amounts of areas composing alpine zones (Nagy and Grabherr, 2009). For example, numbers of species appear relatively low in isolated alpine regions such as in New Zealand (Mark and Dickinson, 1997) and in tropical Africa (Hedberg, 1997). The size and composition of the regional pool of plants and the time these have had to evolve and adapt to alpine climatic conditions clearly are important in determining the richness of alpine sites.

Our knowledge base of the alpine systems is also a function of geography. Studies of the patterns and controls on alpine plant diversity are relatively common for Europe where an entire volume has been dedicated to the subject (Nagy et al., 2003). That work has been updated with a volume on alpine biology that reviewed alpine habitats on most continents (Nagy and Grabherr, 2009). In North America, syntheses are fewer and are often site-specific (Bowman and Seastedt, 2001; Williams et al., 2015). A modest number of northern Eurasian studies were available and summarized several decades ago (Wielgolaski, 1975), but information accessible to English readers on alpine areas in China and Mongolia have only become common in the last two decades (c.f., Feng et al., 2006; Wang et al., 2013; Dong and Sherman, 2015).

Among the fairly safe generalities about the patterns of plant diversity in the alpine is that that lichens and bryophytes increase in richness with latitude while vascular plant richness declines (Virtanen et al., 2003). There is also strong support to show that soils with higher pH, which contains higher plant-usable cations and less soluble aluminum, have higher local and regional richness

values (Körner, 2003; Virtanen et al., 2003; Gasarch and Seastedt, 2015a). High local species richness is found in drier zones of the alpine. Marini et al. (2007) found alpine species richness to be highly positively related to the presence of “small stress-related species” which tend to be found in drier portions of the alpine. For example, in the Tatra Mountains, Czortek et al., (2018) found averages of over 40 species in dry meadow plots, compared to 20 or less species in plots located in wetlands and snowbeds. These trends are very similar to a dry to wet meadow gradient found in the Colorado Rockies (Bowman and Swatling-Holcomb, 2018) and elsewhere.

Effects of grazing on alpine richness and productivity have the potential to produce the same curvilinear response documented for many grasslands, that is, responses can be positive, neutral, or negative depending upon the intensity and frequency of grazing. If light to moderate grazing reduces the abundance of dominant species, then some increase in plant evenness and diversity is expected, and local richness may also increase. In contrast, heavy grazing and especially long-term moderate to heavy grazing will reduce both richness and productivity (Lu et al., 2017). Overgrazing has occurred in the past in most alpine systems and these grazing legacy effects may still be influencing observed patterns. Similar to abuses caused by road building and trampling, long-term overgrazing damage involves erosion and soil loss. Even smaller herbivores, such as gophers, can have this effect (Sherrod and Seastedt, 2001). Passive revegetation in the alpine (e.g., natural reseeding from adjacent areas), particularly in drier areas, is extremely slow (Ebersole, 2002), so legacy effects of overgrazing on current communities may be significant. Changes in grazing intensity and frequency may also interact with climate changes, enhancing or reducing the more diverse and productive habits found in the alpine (Wang et al., 2012). However, grazing could also prove to be a useful alpine management tool under some scenarios.

The Productivity of Alpine Ecosystems

The amount of carbon fixed into plant biomass per unit area per unit time (NPP) in alpine areas has been measured and reported numerous times since an original global summary by Lieth and Whittaker (1975). Aboveground values for vascular plants can range from zero to over 500 g m⁻² of mass with ranges of 100–300 g m⁻² being most common (Bowman and Fisk, 2001). Belowground production likely exceeds that of aboveground production (Fisk et al., 1998; Körner, 2003) and in some communities is likely more than double aboveground production. Understanding carbon dynamics of the alpine in an era of climate change is clearly a current concern. Most studies to date, however, have focused on the variability of NPP observed across the alpine tundra and the factors that control this variation.

The primary controls on plant productivity are the three potentially orthogonal resources: solar energy, nutrients, and water. Temperature might be considered a secondary control and can control the availability of water by converting plant-available water to ice or water vapor, and can also impose strong constraints on plant functioning via controls on enzyme structure and efficiencies. However, in the alpine, environmental controls interact with one another as well as with the biota, and the result of this produces often complex, localized patterns in plant productivity.

As discussed earlier, alpine regions can include areas that remained ice-free during the last glaciation, such as the 180,000-year-old surfaces found on Niwot Ridge (Bowman and Seastedt, 2001). Older surfaces have the potential to have mature soils that can accrue and store plant nutrients. At the opposite extreme are areas just now emerging from retreating glaciers or soils just now forming in what were nival (above the alpine) zones, producing clear nutrient limitations to plant species presence and abundances (Bueno de Mesquita et al., 2017; Castle et al., 2017). Accompanying this fact are the often substantial topographical constraints of slope and aspect that influence soil formation and fertility. Since soils hold both water and nutrients, generalizations about water and nutrient limitation in the alpine usually require site-specific qualifications, and the extent of soil limitations can vary from none to extreme.

The sensitivity of alpine vegetation to nutrient additions has been studied for many decades (e.g., Wielgolaski, 1975). In that study, vegetation was shown to increase by 4.6-fold after 2 years of a large addition of macro (nitrogen (N) phosphorus (P) and potassium (K)) and micro nutrients (magnesium (Mg) sulfur (S) and boron (B)). Of interest was the finding that the mixed fertilizer outperformed N fertilizer (as nitrate) by a factor of about three. Clearly, the vegetation in that study area experienced multiple nutrient limitations. More recently, scientists working at a global network of sites used a nutrient factorial experiment to identify those nutrients limiting to productivity. The general findings are that N and P, but not K or micronutrients, tend to limit productivity of grasslands, including the alpine (Fay et al., 2015). In alpine soils that have been recently exposed due to receding glaciers, P has been found to be more limiting to plant growth than N (Darcy et al. 2018). The relative magnitude of the response to nutrients is often a site (soil) characteristic, but alpine systems are generally sensitive to both N and P additions, and these additions affect both productivity and plant community composition (Fig. 2; Theodose and Bowman, 1997; Gasarch and Seastedt, 2015a).

How Resource Availability Sculpt the Diversity and Productivity of the Alpine

Integrating multiple resource limitations improves our understanding of the patterns of diversity and productivity seen on the alpine. The alpine topography is capable of generating a plethora of energy and moisture gradients and range in values that, from a vascular plant's perspective, vastly exceed an individual species' tolerance constraints. Changes in energy and water gradients though time generate nutrient and soil acidity gradients that also affect plant community diversity. However, one gets a sense

Fig. 2 A 2×2 m nitrogen + phosphorus plot in a dry meadow alpine located at Niwot Ridge, Colorado. This plot has been fertilized every other year for over 20 years. The dashed line borders have been added to better identify boundaries. The surrounding meadow is dominated by a sedge, *Kobresia myosuroides*, which has now been largely replaced in the plot with a variety of forbs and other graminoid species. Overall plot richness as well as diversity has increased in this plot, but responses to nutrients in other plots and in different moisture regimes can vary. Photo by author.

that water and energy are the primary factors, just as they appear to be in structuring the global diversity of vascular plant species (Kreft and Jetz, 2007). In the alpine, however, the fact that a large percentage of precipitation falls as snow confounds water-energy gradients even further (Billings, 1973). At one extreme the wind-scoured uplands remove most snow before the moisture can penetrate the soil. The soil surfaces of these wind-scoured areas receive substantially more solar energy inputs than surfaces beneath snowdrifts. By amplifying precipitation and light input differences, the topography of the alpine generates water-limited to light-limited (integrated solar radiation over the growing season) gradients that in turn affect soil development and generate plant diversity gradients. Snowfields can, on occasion, last beyond the annual growing season, thereby inhibiting all plant growth in that year. This likely explains, in part, why such a high fraction of alpine species are perennial rather than annual or biennial species.

When the consequences of the topography-climate interaction are expressed in terms of effect on alpine productivity, a curvilinear pattern across the tundra landscape is generated (Fig. 3). This figure might benefit from a third dimension that would explicitly recognize nutrient limitation, such that higher availability of N, P, and in some sites, certain micronutrients, would enhance NPP values. An empirical validation of this model is shown here by summarizing nine years of ANPP from a set of approximately 80 plots measured annually at Niwot Ridge, Colorado (Niwot LTER, 2019; Fig. 4). The production gradient goes from low production endpoints, fellfield or snow bed communities, to the increasing ANPP gradient generated by dry, moist, and wet meadow sites. Wet meadow sites can become free of snow after dry meadow sites, but due to runoff subsidies of water from upland

Fig. 3 Generalized model of site productivity (values in blue) as a function of light availability and snowpack. Extremely windblown sites have maximum light but minimum soil volume, fertility, and water. Snow bed communities, created by massive snowdrifts, have very limited growing seasons and following high snow pack winters may not melt out during the current growing season.

Fig. 4 Aboveground net primary productivity, estimated by aboveground biomass, measured over 9 years at Niwot Ridge, Colorado. Standard errors of the annual mean values are shown.

sites, these do not dry out during the summer as early as dry meadow sites. Hence, growing season duration can be affected by water as well as light availability.

The Relationship Between Diversity and Productivity of the Alpine

Demonstrating a beneficial relationship between diversity and ecosystem services has been somewhat of a Holy Grail mission of ecologists, and one that's been generally successful after decades of study (Isbell et al., 2011; Grace et al., 2016). At the entire biome or alpine community level scale, plant diversity usually correlates with ecosystem services such as plant productivity or carbon sequestration. However, when examined at smaller spatial scales, different patterns exist because of the varying strength of the biotic-abiotic interactions that influence diversity across local resource gradients. If, as suggested here, these gradients are both steep and large, we should expect patterns not seen in more homogenous environments.

Multivariate analyses, path analysis, and structural equation modeling are important tools to understanding both species diversity and productivity characteristics of alpine ecosystems (c.f., Kikvidze et al., 2005; Yuan et al., 2016). However, in applying these tools or attempting to generalize from site findings, the recognition that "context matters" needs to be acknowledged. Often a single variable or mechanism is touted as *the* factor affecting the pattern of interest. Clearly this is the exception rather than the rule in ecology (Belovsky et al., 2004), and this is particularly true when discussing patterns of diversity and productivity of the alpine tundra.

The concept that diversity might be a dominant factor affecting plant productivity in the alpine is intriguing. Since we know productivity declines with increasing elevation or latitude and richness also declines with increasing elevation or latitude, we should expect a positive correlation between productivity and plant species richness or diversity at a scale that includes all alpine sites (Fig. 5). This is correlation, not causation, and only indicates that whatever has a positive effect on diversity may also have a positive effect on productivity. At smaller spatial scales such as the site level, plant responses are dominated by the combination of resource

Fig. 5 Plant richness or plant diversity (values in blue) as a function of light and snow pack. The generalized model follows that of productivity except that maximum richness and diversity occurs in fellfield or dry meadow communities where positive species interactions such as facilitation and reduced competition among neighbors may outweigh negative interactions caused by absolute resource limitation.

availability, resource heterogeneity, and the diversity of plant growth strategies used to exploit resource availability. Using the same plot data shown in Fig. 4 to produce a richness-ANPP curve, a nonsignificant, negative relationship exists between productivity and plot richness, a response similar to that shown for site B in Fig. 5. As described earlier, at this site the highest species richness in plots is found in fellfield or dry meadow sites and declines from dry to wet plots. Here, as elsewhere, richness declines to lowest levels where rock cover and winds preclude water availability (e.g., Kikvidze et al., 2005). This produces a skewed version of the conceptual model that described production (Fig. 6). Such a response can be generated, as suggested by Marini et al. (2007), by an abundance of small species adapted to the dry and wind-scoured areas of the alpine, by changes in how the plants affect other plant species across a resource gradient, or both of these alpine species characteristics.

Kikvidze et al. (2005) and Bowman and Swatling-Holcomb (2018) demonstrated that plant species interactions consistent with concepts of facilitation or competition are not uniform across resource gradients in alpine communities. Those authors noted that net positive interactions tended to be more common in low resource, low production areas such as fellfields and dry meadows. They noted that certain species function as facilitators, and those plants may occur only in a subset of alpine communities. Conversely, the competitive characteristics of individual species can also vary across habitats that have relative large resource gradients. Certain species, such as the clover, *Trifolium dasyphyllum*, a plant associated with nitrogen fixation and found only in drier habitats, increase the plant diversity in their immediate surroundings (Thomas and Bowman, 1998). The strength of negative and positive feedbacks produced by the dominant forb *Geum rossii* can vary across the resource gradients that it inhabits (Bowman and Swatling-Holcomb, 2018). In contrast, the alpine grass *Deschampsia cespitosa*, a species with relatively large growth capabilities in the alpine, exhibits strong competitive effects and can suppress species diversity (Suding et al., 2008) but tends to occur only in the more productive habitats. Thus, plant traits influence local richness, and the tendency for negative interactions in more resource-rich areas appears to be a common trait across herbaceous communities (Grace et al., 2016).

Abiotic factors can also contribute to facilitation of species. Rocks can contribute to the fitness of alpine species in wind-scoured areas by reducing wind damage and potentially providing snow cover and additional moisture in leeward areas. Such sites are also important for plant recruitment and community development in primary succession following deglaciation (Jumpponen et al., 1999). Unlike nurse plants, rocks will not subsequently compete with neighbors for resources, so while the interactions between species can be transitory over a growing season, the abiotic-biotic interaction within a single area remains fixed. However, similar to alpine plants switching from positive to neutral to negative feedbacks, a rock in a wet, sheltered area clearly does not function in a similar manner to one found in a fellfield. Thus, both biotic and abiotic factors can influence the abundances and diversity of neighboring plant species, and the intensity and outcomes (+, 0, –) of these factors can vary across the alpine landscape.

The Alpine in the Anthropocene: Anticipated Changes in the Coming Decades

Among the human-generated factors we classify as threats to alpine communities are the introduction of invasive species, changes in atmospheric inputs including such materials as dust, nutrients, and organic and inorganic pollutants, climate warming, and changes in the seasonality and amounts of precipitation. The well-documented warming trends for most alpine areas are arguably driving plant species uphill and potentially off the tops of the mountains. However, consistent with the finding that alpine diversity and productivity are controlled by multiple factors and the interactions among these factors, we should anticipate that predicted changes for the alpine will be strongly modified by site-specific responses.

Fig. 6 The regional and site-specific relationships proposed for alpine productivity in relation to alpine species richness or diversity. In the lowest productive sites (Site A), there is little to no relationship between these variables. Under more fertile soils or more benign climates, alpine the relationship becomes curvilinear or negative as competition for light in the most productive plots reduces local richness (Sites B, C).

Introduced plant species are now appearing in the alpine where they were not found decades ago (McDougall et al., 2005). The concern here is species displacement, species extirpations, and the loss of desirable ecosystem services such as carbon sequestration provided by those species. As noted by Alexander et al. (2016), the numbers of nonnative species already present or seen as current potential invaders is relatively modest compared to warmer ecosystems, but with warming, invasive species already established at lower elevations may indeed move upslope into alpine areas. Management practices to discourage both undesirable native and introduced species may be feasible, given that cold-adapted invasive species have, to date at least, been few. However, management also must deal with the changing baseline in human land use practices, climate and atmospheric chemistry drivers.

Human-caused acid rain, a major concern particularly towards the end of the last century, affected soil acidity (Krug and Frink, 1983), a known control on alpine plant richness and diversity. This threat was replaced with somewhat similar concerns for N deposition in alpine communities (Bowman et al., 2015). When atmospheric N deposition accumulates in ecosystems, there is a propensity for soils to also become more acidic, even if the precipitation itself is not strongly acidic. While sites may increase in productivity from the fertilization effect of plant-available N, the acidification process may subsequently produce longer-term, negative effects on plant growth and have negative and long-term effects on plant diversity (Bowman et al., 2018).

Nitrogen fertilizer studies tend to show that graminoids benefit more from N additions than forbs (e.g., Theodose and Bowman, 1997; Gasarch and Seastedt, 2015b). This is believed to be due, in part, to the very conservative growth strategies possessed by alpine forbs. Forbs exhibit “preformation of tissues” and produce embryonic structures that do not emerge as aboveground foliage for 3 years (Diggle, 2002). Thus, when a large nutrient source is added, growth is limited to the number of structures created in previous, potentially low-nutrient years. Graminoids, in contrast, can be more opportunistic and produce more tissue that become leaves and stems in a current growing season. Thus, this rapid growth response can contribute to greater competition and suppress forbs under high resource availability. Of some interest, however, is that additions of both N and P may slowly increase dominance by at least a subset of forbs in some areas of the alpine, suggesting a more important role of P in the structure of alpine communities (Venterink, 2011; Darcy et al., 2018).

Enhanced dust deposition resulting from droughts and inappropriate human management of low elevation, semiarid and arid regions also is affecting alpine communities found at considerable distances from these sources (Steltzer et al., 2009). While there is reason to believe this dust contains materials that buffer acidity and add soil nutrients to alpine communities, the material also affects seasonal snow dynamics by greatly reducing snow albedo and speeding melt-off (Neff et al., 2008). Enhanced dust deposition therefore is an amplifier of climate warming effects.

In a warming world, plants adapted to the colder conditions of the Pleistocene and Holocene can be expected to decline in abundance (Theurillat and Guisan, 2001). Cold-adapted species are at risk (Gottfried et al., 2012) and low-statured plants may be more vulnerable than others (Bjorkman et al., 2018). Climate warming is allowing trees to move uphill in some areas (Leonelli et al., 2011; Rixen et al., 2014), and community sensitivity to change can be a function of elevation (Rosbakh et al., 2014). In alpine regions with both warming and ample precipitation, upward movement of more temperate- or boreal-zone species is a reasonable expectation (Boutin et al., 2017). However, wind, water or winter temperature limitations may preclude that activity in at least some areas (Harsch et al., 2009; le Roux et al., 2013; Moyes et al., 2013). Meanwhile, there is strong evidence that alpine vegetation is moving up in elevation (e.g., Chen et al., 2011), limited now by a combination of soil development, nutrients, and microbial processes (Bueno de Mesquita et al., 2017). Between these endpoints, dynamic changes in vegetation composition and productivity are underway due to a combination of climate and atmospheric chemistry impacts (Bueno de Mesquita et al., 2018). Documenting these changes usually requires the collection of multiple decades of data; measurements over shorter periods have found that vascular plant communities at individual sites or mountain ranges show some resilience to climate change (Gottfried et al., 2012; Spasojevic et al., 2013; Vanneste et al., 2017).

At a landscape scale, there is reason to believe that climate warming will have a neutral to positive effect on alpine plant richness (Sommer et al., 2010; Wehn et al., 2014). A major unknown involves how the seasonality and amounts of precipitation will change in association with warming trends. Regional warming can result in more high-elevation precipitation deposition (Williams et al., 2015), but a higher percentage of that moisture falls as rain rather than snow, and surfaces can have higher evapotranspiration rates. Without the snow cover, the freeze-thaw patterns and phenology of plant growth can be affected, and dry-downs during the growing season could also affect plant phenology (Ernakovich et al., 2014). Under this scenario, Sommer et al. (2010) identify concerns where species reductions are possible, especially when species well adapted to cold and low nutrient conditions must compete with generalists better adapted to warmer, higher nutrient conditions. In North American alpine and arctic areas, “shrublandification,” the process whereby willows or other shrubs can successfully invade herbaceous systems such as alpine meadows, has been identified as problematic (Kudo et al., 2011; Myers-Smith et al., 2011; Formica et al., 2014).

The fate of alpine regions in the 21st century remains uncertain, but observations to date allow for some predictions. What happens if we impose directional warming on the productivity and diversity patterns shown in Figs. 3 and 6? One concludes that some of the species and some of the communities within the alpine would benefit while some would be harmed. The directional drivers could certainly push these communities uphill, provided higher ground exists and can provide areas for vegetation colonization. As growing season length is affected by temperatures, water, snow duration, and irradiance, communities will change. Concurrent effects of atmospheric N and dust deposition, in conjunction with an adjacent, regional pool of plant species able to exploit new conditions, will add further confounding effects. Finally, all of these variables will be amplified or attenuated by existing soil fertility status. The large and steep resource gradients and local heterogeneity in soils and plant community composition suggest that the alpine will remain both a bellwether for change and excellent outdoor laboratory to study factors controlling vegetation change for some time to come.

Abstract

The term “treeline” refers to the natural high elevation or polar limit of tree growth, irrespective of the tree species. Thus, the treeline is a limit of the life form tree, with trees defined as single stemmed, upright woody species taller than an adult person. This life form boundary occurs globally wherever the seasonal mean temperature declines to c. 6 °C and the length of the growing season is at least 3 months. The position of this treeline isotherm is near sea level in the Arctic and can exceed 4000 m in the subtropics and tropics. It commonly is higher in drier and lower at more humid conditions. Human land use (logging, pastoralism) or disturbances (fire, erosion, avalanches) can cause trees to be absent from the climatic treeline. The reason why trees reach a thermal limit, beyond which alpine or arctic, small stature plants do well, has to do with the coupling of tree crowns to atmospheric circulation, while small plants profit from solar heating near the ground.

The Life Form Concept

Biologists have developed two ways to categorize the overwhelming diversity of organismal life: (1) the concept of genetic similarity or relatedness, which yields species, genera, families etc. and (2) the concept of life form, that is grouping the species into morphological categories, which in the case of plants, yields herbs, shrubs, lianas, or trees. This contribution is on the *life form trees*, irrespective of the species or other taxonomic unit to which a tree belongs. Before a tree species has grown to tree size, it passes through the stages of seed, seedling, sapling and the term “tree” applies only after it clearly exceeds the size of shrubs. Thus, a tree is an upright, single stemmed woody plant that has become taller than an adult person. This way, the shoots and leaves experience temperatures that a weather station might measure 2 m above the ground. Experts talk about “aerodynamic coupling to the atmosphere.” In contrast, small stature plants, including tree seedlings, thrive close to the ground, where the climatic conditions can be quite different from those in the free air at 2 m above the ground. It can be much warmer when the sun is out, and such small stature vegetation is sheltered from free air circulation (wind). Hence, low stature plant communities are partly decoupled aerodynamically from the climatic conditions at 2 m height. This distinction is central to the following assessment of the treeline phenomenon.

Definition of Treeline

When the climate becomes very cold, as happens at high, sub-polar latitudes or at high elevations in mountains, trees disappear from the landscape and only small plants can thrive on the land beyond the limit of trees (because they profit from the warmth near the ground). Under undisturbed, natural conditions and provided there is soil and sufficient moisture, trees can grow till they reach a low temperature limit, and the line connecting the most northern or the highest elevation groups of tree individuals is called the *climatic treeline* (Körner, 2012). The upper limit of the closed montane forest is the forest line (called timberline in the older literature), and the position of uppermost isolated saplings, often distorted (see below), is the tree species line, exceeded only by scattered seedlings in sheltered microhabitats that may be found several hundred meters above the treeline. The entire transition zone from the montane forest to the highest elevation saplings is called the *treeline ecotone*. This ecotone may be narrow (sharp tree-line) or gradual and/or fragmented, depending on regeneration stage, disturbance regimes and topography.

If there is insufficient water, as in mountains of hot deserts, or if soil is missing (bare rock), plants cannot grow and there is also no climatic treeline. Under conditions that are so cold that trees approach their range limit, the minimum required annual precipitation for tree growth is 250 mm (Paulsen and Körner, 2014). Most commonly, precipitation is higher than 250 mm in such high elevation or polar regions so that drought does not prevent tree growth (but it may slow tree growth). Under such conditions, the range limit of trees is set by temperature (see below). Wherever mountains are sufficiently high and receive more than 250 mm of

precipitation, a natural climatic treeline is formed (Fig. 1). The elevation of the treeline can be close to sea level in the Arctic, it may be at 2000 m asl in cool temperate zone mountains, or it may occur around 4000 m elevation near the equator. The highest locations of groups of tree-size individuals are found in the dry continental mountains of Bolivia and Tibet (4800–4900 m elevation).

Yet, it is not elevation as such that is important, but the air temperature that is associated with elevation. The record high elevation treelines mentioned above reflect regional climatic anomalies (a very high position of the treeline isotherm; see below). On average, air temperature declines by 0.55 degree per hundred meters of elevation. So, treeline elevation rises progressively from geographical high latitude (the arctic treeline) to the tropics. There is no Southern Hemisphere polar treeline at sea level, because the continents do not reach far enough into high southern latitudes to reach the critically low temperature for tree growth. The southern tip of South America lies at 56°S, a latitude far too warm to prevent tree growth.

Treeline is a global phenomenon (Fig. 1). At least 100 tree species belonging to different plant families are able to grow at tree-line. In the Northern Hemisphere treeline is composed mostly of species belonging to the Pinaceae (conifers such as pines, spruces, larches, firs or junipers), Betulaceae (birch and alder), or the genus *Sorbus* (rowan, family Rosaceae). In the Southern Hemisphere these are Nothofagaceae (southern beeches) or Myrtaceae (eucalypts). In the subtropics a prominent genus in the Andes is *Polylepis* (Rosaceae). In the tropics there is a wide spectrum of taxa that reach treeline. Examples are *Schima* sp. in Theaceae (SE Asia) and Ericaceae (Africa). There are also isolated island regions with high mountains such as Hawaii where no native treeline forming taxa exist (they never made it to Hawaii), but when continental treeline taxa are brought in, they do well and find a limit at the same low temperatures as are found in their native habitats. In some regions, humans have eradicated taxa that would normally form a tree-line, such as happened to *Abies alba* (white fir) in the Italian Apennine. In this case, trees are absent from the potential treeline, and the locally available tree species form a tree species limit set by their specific cold tolerance. An example of this is the tree species limit of *Fagus sylvatica* (European beech) in the mountains of southern Italy. This limit does not fall at climatic treeline.

Fig. 1 Examples of high elevation treelines. (A) The *Nothofagus pumilio* (southern beech) treeline at 1200 m elevation in Patagonia follows sharply the treeline isotherm of air temperature. (B) The treeline in the Baima Mountains of northern Yunnan, China, at 4300 m, is composed of *Abies georgei* (fir) and *Rhododendron*. (C) The treeline in the central Alps of Switzerland at 2300 m, composed of *Pinus cembra*, is fragmented by avalanches and century long pastoralism. Note the avalanche track is filled with *Alnus viridis* krummholz, that tolerates heavy snow loads.

Fig. 2 Where soils are missing, trees cannot grow, irrespective of elevation. In such cases, trees are absent from the climatic treeline as is the case in this example from Kinabalu in Borneo, where *Schima brevifolia*-dominated patches of forest reach only 3700 m elevation, 100–150 m below the climatic tree limit.

These examples of artificial treelines is a central problem in the treeline debate: a treeline can only be defined on the basis of biological principles (see below). In regions where humans cut or burned trees, where avalanches wiped out stretches high montane forest, where soil has been eroded to the bedrock surface (Fig. 2), and where no taxa are regionally available that are physiologically fit to grow at the climatic treeline, then there is no visible treeline in the mountain landscape. The treeline concept loses its meaning, when the next-best forest edge is termed treeline. This means that the actual presence of trees is often a poor indicator of the line at which the tree life form reaches a natural low temperature limit. Trees may be absent from the treeline for many reasons. A treeline concept founded in biological principles must refer to “potential treeline,” a line where trees could grow if they were “allowed” to (hence are not cut, burnt or find substrate to root in). It makes no sense, scientifically, to address any high elevation or high latitude forest edge as a treeline, if the local disturbance regime is not known. This also means that treelines cannot become “depressed,” but they will follow the regional climatic regime (the treeline isotherm), provided trees had not been removed from the line by disturbance.

What Determines Undisturbed Treeline Position?

Because the alpine belt above the potential treeline is defined by the natural absence, of (trees), the treeline defines the biogeographic boundary between the montane and the alpine belt. The montane belt remains naturally forested as long as moisture permits. Because this prominent vegetation boundary is formed so consistently around the globe, the question arises concerning the identity of the common driver of treeline position. Given that geology, patterns of precipitation and atmospheric pressure differ considerably between subarctic treelines near sea level and treelines at 4800–4900 m elevation in Tibet or Bolivia, a critically low temperature remains the only remaining factor common to all undisturbed treelines. This was confirmed first by scaling air temperature from nearest weather stations to treeline elevation (Körner, 1998), and was refined later by obtaining temperature records from sites at treeline at various latitudes (Körner and Paulsen, 2004), and finally, by correlating treeline position as seen from satellites with a climatic envelope of treelines modeled from temperature and precipitation data derived from a climate data base for across the globe (Paulsen and Körner, 2014). It turned out that natural, climatic treelines are established where the mean air temperature during the growing season is around 6 °C, irrespective of whether the growing season lasts 3 months (the minimum length required for tree growth), or 12 months in the equatorial tropics. This hints at a direct impact of low temperature rather than an influence of season length. Further, the influence must be a gradual action of temperature on metabolism and growth, because low temperature extremes (absolute minimum temperature, freezing damage) vary so much across the globe that the treeline pattern we observe in nature could never be established.

The knowledge of a region’s growing season’s mean temperature allows the prediction of regional treeline elevations. The only other condition affecting treeline is that the growing season must not be shorter than 3 months, as defined by the number of days per year with a daily mean temperature of at least 1 °C (Paulsen and Körner, 2014). The precision of this prediction is 10 m of

elevation in oceanic islands such as New Zealand (very stable and predictable isotherms) and 78 m of elevation across all mountains of the world. This error term is largely related to the limited reliability of climatic data for remote mountain areas. Thus, the low temperature treeline is the best defined (and most predictable) biogeographic boundary globally, and it can serve as a reference line for other climatic vegetation boundaries at lower elevations (Körner et al., 2011, 2017). The predictive power of climatic data for treeline position can also be used to locate the position of the treeline isotherm (and thus the lower edge of the alpine life zone) in regions that had become entirely deforested (Noroozi and Körner, 2018).

Why is the Climatic Treeline Where it is?

A conclusive biological explanation for the position of tree limit at the 6 °C isotherm of seasonal mean temperature is not yet available, however there are several factors that can be ruled out, whereas others hold promise. As mentioned above, freezing tolerance can be ruled out, given that the global pattern of treeline position does not match a common freezing regime. The rate of photosynthetic carbon acquisition (CO₂ uptake) can be ruled out, because at 6 °C, leaves of cold-adapted trees reach 50–70% of their maximum rate, and still acquire carbon at a rate of about 30% at 0 °C. Trees cannot grow in freezing temperatures, that is they cannot build new cells and differentiate tissues (e.g. Rossi et al., 2007; Alvarez-Uria and Körner, 2007). Because of that discrepancy between the high rates of photosynthesis (sugar production) and the poor ability to invest these sugars into new structural growth, trees at treeline accumulate rather more reserves (e.g. starch) compared to trees at lower elevations, and there is no indication whatsoever that treeline trees are lacking in carbohydrates (Hoch and Körner, 2012; Fajardo et al., 2012). So, the most likely mechanism through which tree life is constrained when it gets cold is the lack of ability to produce new tissue, both through the cambium (tree ring formation) and apical meristems (length growth of shoots).

It had also been discussed whether cold soils at high elevation could constrain the nutrient cycle and cause trees at treeline to grow so slowly that decay exceeds new growth and thus, sets a tree limit. However, trees at treeline are not generally found to suffer from malnutrition (Birmann and Körner, 2009; Mayor et al., 2017), and such a constraint would also equally affect shrubs above treeline. Moreover, soil nutrient provision also depends on bedrock quality, weathering, topography and moisture regime, none of which are tied to an isotherm. Hence, soil driven tree limits would never follow a globally uniform temperature limit, but reflect local soil conditions, which is not the pattern seen across the mountains of the world. It is a truism that all plants in the wild do not exhibit optimal growth in terms of nutrition, that is, they do not achieve a maximum growth rate that would be possible when fertilizer were added. Indeed, trees growing close to treeline are no different from any other trees in that soil nutrients constrain growth, and thus, they do grow faster when nutrients are added (Möhl et al., 2019). Yet, this growth stimulation does not mitigate the impact of low temperature that sets the ultimate elevational limit to tree distribution. When trees grow at their absolute thermal limit, the addition of nutrients cannot alleviate the thermal growth constraint (Hoch, 2013). Quite clearly, nutrients do not set the position of the treeline (Mayor et al., 2017), although they do constrain the rate of tree growth.

Thermal growth constraints are not tree-specific, but hold for all cold-adapted plants. However, as tree saplings grow to heights above the low stature ground vegetation, which is able to trap solar heat, they experience the free atmospheric air temperature and cannot “produce” their own warmer microclimate as alpine plants do by forming dense low stature stands (Fig. 3). In essence, it is the exposure to ambient air temperature that puts the tree life form on a losing track when it gets cold, whereas low stature alpine plants can decouple from the temperature of the free atmosphere and “engineer” their own, milder microclimate near the ground. This explains why trees are hit first when it gets cold along elevational or latitudinal gradients (see first section). Paradoxically, life conditions are clearly better (warmer) for alpine dwarf shrubs and heathland above the treeline than for treeline trees

Fig. 3 Trees experience a colder environment than do low stature plants, as illustrated by this thermal image. Low stature vegetation accumulates heat under solar radiation, but the crown temperature of trees at treeline is essentially the same as the air temperature 2 m above the surface.

(Körner, 2007). Thus we see that the treeline phenomenon is related to tree architecture, the open nature of which does not permit significant departures from air temperature. This also explains why undisturbed treelines follow isolines of elevation across often rough mountain terrain like the shore line of an alpine lake.

Krummholz

The treeline is rarely abrupt. Trees gradually get shorter until no upright growth is possible and the tree limit is reached. Beyond treeline, one may find deformed, shrub-shaped trees (so called “krummholz”) that profit from self-shelter and moderate heat accumulation among the dense thicket of branchlets. Such shrubby tree individuals can even form clones with layering branches that build adventitious roots (Körner, 2012). Should the climate warm, these shrubby individuals could become upright trees. In contrast to such deformed trees, there are also genetic krummholz species. These are taxa that exhibit a life form intermediate between tree and shrub. Such krummholz taxa can exert severe competition to tree recruitment and can even become so dominant that trees become suppressed in the treeline ecotone (Fig. 4). Examples are *Pinus mugo* and *Alnus viridis* (European mountains), *Pinus pumila* (Japan), and many species of *Rhododendron* in SE Asia.

Tree Recruitment

In all cases, there must be a successful tree seedling before there can be a tree. It commonly requires thousands of seeds and hundreds of tree seedlings to produce one mature tree, a rule that holds for any forest, including those at their high elevation limit. The early life stage is particularly vulnerable in all organisms. The randomness of the environment adds to the lottery of early tree life. Safe and unsafe recruitment niches, snow mold, disturbances by animal browsing, trampling and erosion, top soil desiccation and seed bed overheating, ground frost, etc. keep most seedlings from becoming a tree. It is thus important to ascertain the degree to which early life stage success can have an influence on treeline position and whether the risks discussed above are higher at treeline than elsewhere. While the globally consistent treeline isotherm would not provide much leeway for a site-specific recruitment success, recruitment dynamics in the treeline ecotone are likely to contribute to the shape of treelines at the scale of several tenths of meters of elevation. Likewise, periodic seedling success will influence the state of tree demography (age structure) in the uppermost montane tree assemblages.

From the previous sections it is clear that tree seedlings in treeless patches within and above the treeline ecotone experience warmer conditions than these individuals will eventually experience when they have grown above the shelter of grasses and dwarf shrubs close to the ground, as they enter the sapling life stage. This explains why tree seedlings can be found far above treeline (Fig. 5). So, the direct physiological influence of low temperature is the least likely factor to constrain tree seedlings. Success of seedlings at and above treeline appears to relate to a trade-off between becoming out-competed by dense, low stature alpine vegetation on the one hand (e.g. Angulo et al., 2019), and the risks of life on bare spots (no shelter) on the other hand. On open ground, small seedlings are at great risk of becoming overheated. They are also subject to top soil dehydration, combined with the deleterious effects of intense solar radiation (Cui and Smith, 1991; Germino and Smith, 1999; Bader et al., 2007). Such risks are likely to be even greater for tree seedlings at low elevation, compared to those at treeline. Also, wind-swept mountain ridges are bad places for seedlings to recruit without shelter (McIntire et al., 2016; Renard et al., 2016). Even in the tropics open terrain above treeline exerts a risk of damage by ground frost in clear nights (Rehm and Feeley, 2015).

Fig. 4 Examples of genotypic “krummholz” species that may suppress and replace trees in the treeline ecotone. (A) *Pinus mugo* at 2000 m in the Austrian Alps with scattered *Picea abies* individuals. (B) Vast *Rhododendron* thickets out compete *Abies georgei* in Northern Yunnan, China. Deformed individuals of otherwise treeline taxa may also form krummholz above the treeline.

Fig. 5 Tree seedlings far above treeline profit from shelter among small stature alpine plants and rocks. Temperatures are much warmer close to the ground compared to a tree canopy, causing seedlings to be less constrained by low temperature than fully-grown trees. Once shoots protrude from the warm boundary layer they become damaged. The examples shown here are from the Swiss central Alps at 100 m (*Larix decidua*) to 400 m (*Pinus cembra*) above treeline.

Because tree recruitment is commonly not continuous but occurs in waves supported by mass fruiting events, combined with several favorable follow-up seasons, a seedling census at one point in time may not be representative of the long-term situation. The maintenance of treeline may require only one or two successful recruitment waves in a century. Because of the resulting demographic bias, one may find treelines in various stages of regeneration or mortality, reflecting the legacy of events that may date back more than 100 years. Disturbance regimes such as avalanches, fire, wind break, pastoralism or wild animal browsing cycles complicate the interpretation of tree demography at any one point in time. As is often the case in ecology, things that look simple from a great distance and at large scales become quite complicated at finer scales of time and space. Recruitment—related processes are thus likely to affect the small scale appearance and demography of the treeline ecotone (Holtmeier, 2003; Bader et al., 2007), but will hardly affect its climate—driven elevational position as long as no disturbance regimes come into play.

Future Treelines

Given the tight coupling of treeline position with temperature, treeline elevation has changed in response to past climates and it will continue to do so in the future (Körner, 2012). Warmer climates will cause treeline trees to grow faster, a trend already evidenced for recent decades (Paulsen et al., 2000; Rolland et al., 1998), and treelines will move upslope. But given the stochastic nature of recruitment, this is not likely to be a continuous process, but rather episodic, varying with topography and disturbance regimes (Holtmeier and Broll, 2005). Since treeline trees are not commonly carbon limited (Hoch and Körner, 2012) the rise of atmospheric CO₂ concentration itself is unlikely to facilitate a general further stimulation of tree growth. However depending on local settings, species and life stage, and concurrent warming, a transitory CO₂ fertilization effect may come into action. For instance, a CO₂ enrichment experiment with sapling-sized trees at treeline in the Swiss Alps revealed that *Pinus uncinata* is entirely unresponsive to a CO₂ enriched atmosphere (555 ppm CO₂), whereas *Larix decidua* took advantage from such a step change in CO₂ concentration during the early part of the 9 year experiment. This was particularly the case during warm years, which could affect the competitive interaction between species (Dawes et al., 2011). A warmer climate could also increase the intensity and duration of insect outbreaks such as the larch bud moth (Baltensweiler et al., 2008). Since treelines are affected by land use around the globe, changing land use practices are likely to supersede climate change effects in many mountain regions. Land use pressure (and incurred fire frequency) can devastate upper montane forests (Hemp, 2005), and land use abandonment may cause undesirable, rapid shrub encroachment in formerly cleared land that prevents tree recruitment at treeline (Hiltbrunner et al., 2014).

Summary

The tree life form suffers aerodynamically from its tall and open architecture when the weather gets cold. This is the reason why trees find a low temperature limit at lower elevation (and lower latitude) than low stature alpine (arctic) vegetation. Because of their exposure to the free atmospheric circulation, the high elevation tree limit follows a line (the treeline), once a critical air temperature is reached, a pattern that is not seen in low stature vegetation, the distribution of which is more strongly shaped by topography than by elevation. Trees are not physiologically inferior to alpine plants, but they experience harsher climatic conditions once they grow

taller than the shelter provided by grasses and shrubs (or rock fields) within the treeline ecotone. The action of low temperature impacts tissue growth directly (the meristems) rather than photosynthetic carbon acquisition, and freezing tolerance provides no explanation of treeline position at a global scale. Recruitment can be severely constrained when seedbed shelter is lacking. Because the position of undisturbed treelines is set by temperature, climatic warming will inevitably cause treelines to move upslope, yet the dynamics of this process depend on stochastic events, and thus will vary from place to place.

Abstract

The three grass-dominated mountain top formations in South America are the Puna, the Páramos and the Campos de altitude. The first two span a wide latitudinal range in the Andes, while the Campos de Altitude are found in relicts in the higher areas of the Brazilian Atlantic forest. They are all dominated by C3 tussock grasses and harbor high levels of endemism. Remarkably, they share a number of grass genera despite the geographical distance between the Andes and the Atlantic forest. All these alpine grasslands also harbor iconic fauna and provide key ecosystem services. Moreover, they share a history of intense human-induced disturbance, which has resulted in high degradation and fragmentation rates. Climate change is exacerbating the threats to these ecosystems because they are systems driven by specific adaptations and narrow niches of species, thus small environmental changes can cause a re-assemblage of species communities and increase fragmentation. Lastly, they remain poorly studied compared to other grasslands ecosystems, and we identify the main knowledge gaps that should be urgently addressed if we aim to conserve these precious systems.

Introduction

Tropical grasslands are estimated to occupy about 15 million km², a similar area to that of tropical forests (Olson et al., 1983). However, they are often misclassified as woodland or savannas (Hall and Scurlock, 1991) or as degraded systems (Parr et al., 2014). Moreover, much of their original extent has been converted to crops, mixed farming and artificial pastures.

South America is one of the continents in which the study of grasslands has been most neglected. While the continent is well renowned for its vast biodiversity, this is often associated with its tropical and subtropical moist rainforests - particularly the Amazon. However, South America harbors 11 of the world's 14 biomes defined by Dinerstein et al. (2017) including an extensive variety of grassland ecosystems, such as the llanos and open savannas.

This paper reviews some of the most iconic yet perhaps most neglected ecosystems: the tropical alpine grasslands in the Andes and the Atlantic forest: the Puna, Páramos and Campos de altitude—the three grass-dominated mountain top formations in South America.

Mountains of South America and Their Grasslands

The Andes is the primary mountain range in South America and harbors the largest number of endemic plant and animal species in the world (Myers et al., 2000). The Andes provide a wide range of ecosystem services to about 100 million people living in both high-altitude areas and in the neighboring lowlands (Buytaert et al., 2011). Tussock grasslands span the entire tropical Andes at elevations above 3000 m asl and are termed either Puna or Páramo depending on their location and species composition, as reviewed in the next section. Humans have co-existed with these natural grasslands in the Andes since pre-Inca times (Ellenberg,

1979) but anthropogenic pressure has significantly increased in the last century (Spehn et al., 2006). For example, in the Northern Andes, changes in agricultural practices have caused extensive ecosystem degradation (Sarmiento et al., 2003), and intensive grazing and burning have caused several native species to disappear (Premauer, 2004). Human transformation of landscapes is also affecting the hydrological regulation capacity of the alpine regions in the Andes (Podwojewski et al., 2002; Crespo et al., 2010).

Besides the Andes, the Atlantic Forest along the coast of South-Eastern Brazil contains the Serra do Mar and Serra da Mantiqueira mountain ranges comprising the Campos de altitude (Highland grasslands) above an elevation of 1500–1800 m. The Atlantic forest also has exceptional levels of endemism, with an average of 50% and regionally up to 95% endemic species (Morellato and Haddad, 2000). However, this ecosystem has been reduced to only 7–14% of its original extent (Ribeiro et al., 2009). The Campos de altitude are azonal formations above 1500/1800 m within the Atlantic forest, containing a mosaic of shrubs, bunch-grasses, bamboo and a sparse herb understorey (Safford, 1999a,b). They are often compared to the Andean Parámos and despite their small extent, their patchy assemblages and the mounting threats, biodiversity is exceptionally high (Safford, 1999a,b) (Fig. 1).

Fig. 1 Map of the alpine grasslands of South-America according to the definition adopted in this review and overlaid with the outlines of the Myers eco-regions of the Puna and Parámos (Myers et al., 2000). Map produced from MODIS Land Cover Map (classes 7, 9 and 10 for Parámos and Puna grasslands; classes 9 and 10 for Campos de altitude) masked with the SRTM Digital Elevation Model based on an elevation above 3000 m asl for the Andes and above 1500 m asl for Campos de altitude.

Grasslands

Types of Tropical Alpine Grasslands and Their Ecology

We define alpine tropical South American grasslands as intertropical ecosystems dominated by herbs and shrubs found between the tropics of Cancer and Capricorn at elevations above 3000 m asl in regions near the equator, and above 1500 m asl in higher latitudes. According to this definition, South America contains three major tropical alpine grassland regions: the equatorial *Parámos*, the wet and dry *Punas* in the Andes, and the *Campos de altitude* in South-Eastern Brazil. Some authors argue that, due to their intertropical position, the term ‘alpine’ in the Andean context should be replaced by the term ‘tropical andine’ (Lauer, 2018) but, in order to include the *Campos de altitude*, we retain the use of the term ‘alpine.’

Due to their distinct climate and topographic conditions, all three types of alpine grasslands harbor exceptional levels of biodiversity and endemism. The ecological peculiarities of each grassland region are discussed below, with reference to their climate, geology and soil, vegetation (vegetation belts, dominant taxonomic groups and lifeforms, adaptations) and faunal.

Parámos

“*Parámos*” comes from the ancient Spanish word for “an elevated, barren, treeless plateau” (Ramsay, 1992) and is used for ecological formations dominated by grasslands found in the tropical high mountains of all continents; the Andean *Parámos* is by far the most extensive of these, spanning the Northern Andes between Colombia, Venezuela, Ecuador and Northern Peru (Lauer, 2018).

Climate

The *Parámo* climate is tropic-alpine with high diurnal temperature oscillations and relatively low annual variation in temperature, which converges into a temperate climate with more seasonality towards the South (Ramsay, 1992). Despite the North-South variation, the main axis of environmental variation is East-West causing distinct zonation and occurrence of *Parámos*: in the western Andes the *Parámos* extend from 10° North to 10° South, and in the Eastern Andes from 10° North to 30° South (Ramsay, 1992). This large longitudinal extension of the *Parámos* across the Andes results in different exposures to the circulation patterns of the atmosphere, creating large variations in precipitation from 2000–5000 mm (Lauer, 2018). Nonetheless, the *Parámos* are remarkably drier than the cloud forests below (Lauer, 2018). In proximity to the Equator, rainfall at high elevations is infrequent due to the oscillation of the Intertropical Front (Fittkau, 1969). As one moves South, rainfall becomes more seasonal (Ramsay, 1992). This rainfall seasonality is a critical factor for occurrence and character of *Parámos*, with a 3-month dry-period in Colombia, and 4–6 month dry-period in Venezuela. Frost is prevalent in the *Parámos*, with the number of days of frost increasing sharply around 3300 m at the boundary to the montane forests below. At the upper *Parámos* limit between 4500 and 4700 m asl, up to 100 frost days per year can occur (Ramsay, 1992).

Geology and soil

Parámo soils are mostly dark, acidic, rocky and poorly developed. Inorganic nutrient content is low and high organic content can be only found in the upper horizon. However, varying factors like topography, geological history and altitude result in local variation of soil properties (Ramsay, 1992).

Vegetation

Parámo vegetation is at least four million years old and the long duration of its evolution has given rise to 30 endemic genera out of 300 (10%) (Van der Hammen, 1988). In the Colombian *Parámos*, half of the genera are of either tropical or neotropical origin, while in the Ecuadorian *Parámos*, the lower temperatures and lower humidity favor temperate taxa such as the *Compositae* and *Poaceae* families (Ramsay, 1992).

The *Parámos* occupy the vegetation belt between the upper limit of the montane cloud forest and the snow-line occurring at 4700–4800 m asl (Hess, 2017). Elevation is the main driver for *Parámo* vegetation, and this results in an internal vertical structure with three main *Parámo* vegetation belts: the sub-*Parámo*, the grass *Parámo* and supra-*Parámo*. The shrubby sub-*Parámo* sits above the upper Andean forest between 3500 and 4100 m asl and contains scattered forest fragments and trees. Above the sub-*Parámo* lies the grass *Parámo*, dominated by tussock grasses. Immediately below the snowline, at about 4100 m, the grass *Parámo* converges into the supra-*Parámo*, dominated by mat-forming and cushion plants (Lauer, 2018). Within the vegetation belts, especially in the grass-*Parámo*, local environmental variables and human-induced disturbances cause compositional discontinuities leading to a patchy mosaic of species composition and vegetation structure (Valencia et al., 2019).

The majority of *Parámo* vegetation is dominated by tussocks. Other accompanying growth forms include acaulescent rosettes, upright shrubs, prostrate shrubs, erect herbs and prostrate herbs and, at higher elevations, cushions. Plant species in the *Parámos* exhibit adaptations to the harsh climate and to human-induced disturbances. Many *Parámo* communities contain plants that resprout vigorously following fires and regenerate from below-ground plant parts, as well as from within the tussock bases (Ramsay, 1992). Burning generally creates cyclical patterns of community development and the establishment of some species (such as *Lupinus* cf. *pubescens*) relies on burning. Ultimately, the severity of a fire, established through measures such as the interval length since the last burn, determines the degree of survival. Another adaptation is the resistance to low night-time temperatures evolved by a number of plants, which is largely determined by the growth form (Ramsay, 1992).

Fauna

The main mammals in the Páramos are deer (*Odocoileus virginianus*), and several large predators such as the puma (*Felis concolor*), spectacled bear (*Tremarctos ornatus*) and the Andean fox (*Dusicyon culpacus*). Smaller mammals include rabbits (*Sylvilagus brasiliensis*) and numerous small rodents.

Large bird species include Carrion-feeders like the Condor (*Vultur gryphus*) and large birds of prey. The Páramos provide habitat to 12 species of hummingbirds (*Trochilidae*), the Cordillera Snipe (*Chubbia jamesoni*) and, in the lakes, to ducks and teals, along with populations of introduced trout (*Salmo gairdnerii* and *S. trutta*).

Puna

Westwards and in rain shadow areas, Páramos are progressively replaced by Puna grasslands, a drier vegetation type situated above 3400 m, extending from northern Peru to northern Argentina (Alba Mejía, 2008). The Puna spans over an area of more than 10° longitude and is up to 300 km wide, covering the east and west flanks of the Andes, resulting in different Puna sub-regions, shaped by different levels of humidity: the wet Puna, the dry Puna and the central Puna. The wet Puna spans across the Andean mountains of Peru and eastern Bolivia, while the dry Puna lies in southwestern Peru and north-western Bolivia. The Central Puna grasslands are located on the west-Andean flanks in Southern Peru and East of the Bolivian dry Puna, with an intermediate climate and subsequent unique species assemblages that distinguish it from the dry and wet Puna.

Climate

The wet Puna is characterized by a semi-dry climate with precipitation varying between 500 and 700 mm per year from North to South and annual average temperatures ranging from 5 to 7 °C. The dry Puna receives even lower precipitation, between 250 and 500 mm per year. Average annual temperatures vary from cold to temperate, in a range of <0 and 15 °C (Pulgar Vidal, 2014). At higher elevations, the central Puna has an oligothermic climate with large diurnal temperature ranges and an annual precipitation of less than 700 mm, mostly in the form of hail and snow.

Geology and soil

Most of the Puna ecoregion rests on 6–8 million year old Tertiary and Quaternary volcanic bedrock from the formation of the Andes, with glacial landforms such as moraines present throughout (Whitmore, 1997). The Puna Ecoregion contains Lake Titicaca, the highest lake in the world at 3800 m asl, and an extended salt plain.

Vegetation

Puna vegetation is broadly grouped into the central Andean Puna, wet Puna and dry Puna. The central and wet Puna are dominated by bunchgrass communities, wetlands, small shrubs and trees, and herbaceous plants with a high number of endemic species.

The wet Puna occurs between 3700 and 4200 m asl in the Altiplano and is vegetated by grasses and shrubs. Sedges and rushes dominate wet areas with genera such as *Carex*, *Juncus*, *Oreobolus* and *Scirpus* below 4000 m asl and floating submerged cushion plants above 4000 m asl (Whitmore, 1997). Montane grasslands can be found between 3800 and 4200 m asl in deep glacial valleys, under a greater precipitation regime than that of the wet Puna.

The Central Andean Puna lies between 4200 and 5000 m asl and is vegetated by grasses with prostrate and roseate growth forms, such as *Festuca*, *Stipa ichu*, and *Calamagrostis*. Dry Puna is characterized by xerophytic vegetation and patchy distributions. Harsh conditions of aridity and thin atmosphere, coupled with strong natural disturbances like droughts and frosts, create vegetative adaptations such as particular leaf shapes, very slow growth, stunted forms and high resin content. The genera *Calamagrostis*, *Agrostis* and *Festuca* are common here (Hess, 2017).

Besides these major Puna vegetation belts, there are also azonal formations ('bofedales') with wet grasslands in peat bogs, fens and reed beds vegetated by *Juncaceae*, *Cyperaceae*, and *Asteraceae*. The salt plains feature halophytic shrubs and low herbaceous grasses of *Muhlenbergia* and *Distichlis humilis* (Alba Mejía 2008).

The Puna regions harbor an exceptionally high number of species. Alba Mejía (2008) recorded a total of 1500 plant species, with floristic similarities to the Parámo and Jalca and about 40 Puna-endemic genera. According to Davis et al. (1994) there are 1000–1500 vascular plants on the Peruvian side of the wet Puna alone. Endemic species of the ecoregion are the supu-tola (*Diplostephium tovari*) and the mullu-mullu (*Ribes brachybotrys*).

Fauna

Andean camelids of the Puna include the vicuña (*Vicugna vicugna*), llama (*Lama glama*), guanaco (*Lama guanacoe*), and alpaca (*Lama pacos*). Predators include the puma (*Felis concolor*), and the Andean fox (*Pseudalopex culpaeus*) which prey on rodents like the chinchilla (*Chinchilla brevicaudata*), the Puna mouse (*Punomys lemmings*) and the vizcacha (*Lagidium* sp.).

The dry Puna ecoregion harbors a rich endemic avifauna and many critically endangered species such as the Ash-breasted tit-tyrant (*Anairetes alpinus*) and the critically threatened royal cinclodes (*Cinclodes aricomae*). The suri (*Pterocnemia pennata*) is an emblematic Puna bird species. Puna herbivores have strong incisors to feed on the hard, silicon-rich plant tissues, and they exhibit special skins or plumage as an adaptation to low temperatures and strong winds.

Brazilian Campos de altitude

The Campos de altitude (Highland Grasslands) are found at an elevation above 1500 or 1800 m asl, inserted in the mountain ranges of the Serra da Mantiqueira, Serra do Caparaó and Serra do Mar of the Brazilian Atlantic rainforest biome in South-Eastern Brazil.

Due to their position on mountaintops, they can be regarded as isolated patches or habitat islands within a forested landscape, with different climate conditions than the surrounding Atlantic Forest.

They are distinct from the quartzite Campos Rupestre, located further inland at somewhat lower elevations in a continental climate in Mantiqueira, Espinhaço and associated mountain ranges in central Brazil (Fernandes, 2016). Due to its occurrence above 900 m asl, the Campos Rupestre can be regarded as montane grasslands, mainly shaped by edaphic factors, and are thus not examined in-depth in this article about alpine grasslands. However, their conservation importance should not be underestimated, with a richness of 6000 plant species and some families reaching up to 80–90% endemism (Fernandes, 2016) within an area of only 26,418 km². For the sake of completeness, some additional campos can also be found on Amazonian mountains between 1600 and 2900 m asl. These “Campos de altitude da Amazônia” are dominated by shrubs and herbs such as *Melastomataceae*, *Poaceae*, *Bromeliaceae* (Martinelli, 2007).

Climate

The region has a mean annual temperature of 12 °C, with cool summers and moderately cold winters with frequent frost. The climate in the Campos de altitude is oceanic, and seasonality of rainfall, frost and temperature is high. In the rainy season from November to March, monthly precipitation can exceed 400 mm, while monthly mean temperatures lay between 11 and 13 °C. During the dry season in May–August, monthly precipitation can be as little as 30 mm and monthly mean temperatures are 7–8 °C with 10–15 frost days per month. Thus, summer droughts paired with frost are a main stressor for vegetation but can partially be offset by orographic fog (Safford, 1999a,b). Mean diurnal temperature range is 7 °C. Safford (1999a,b) concludes that the Campos de altitude are climatically similar to the Páramos de Costa Rica, resulting in physiognomic similarities, even though seasonal climatic differences are up to four times greater in the Campos de altitude. The high climatic seasonality results in a high intra- and interspecific diversity of eco-physiological behavior (Scarano, 2002).

Geology and soil

Campos de altitude are found on igneous and metamorphic substrates, mostly of Precambrian age such as granite rocks or Nepheline-syenite (Alves and Kolbek, 2010). Soils are highly acidic and nutrient-poor with soil types ranging from deep, organic mulls, moderately lateritic clays to rare moors (Safford, 1999a,b). Morphological formations include plateaus with rolling, rounded hilltops, deeply dissected stream courses headed in steep amphitheaters, inselberg landscapes, large expanses of bare rock and often high cliffs (Safford, 1999a,b).

Vegetation

Major vegetation associations include (1) grasslands with dispersed shrubs dominated by dwarf bamboo and pampas grass, (2) hydric associations with reed and sedges, and (3) dwarf tree associations and rocky slopes, cliffs and summits with herbs and grasses (Safford, 1999a,b). Due to the low elevational range of just 700 m, vegetation belts are not clearly distinguishable and vegetation is mostly controlled by local topography, the drainage network, and the distribution of soil types (Safford, 1999a,b).

Vegetation consists of a mosaic of graminoids such as tall-stemmed bunchgrasses (*Cortaderia*, *Calamagrostis*, *Andropogon*), sclerophyllus shrubs (especially species of *Baccharis*, *Vernonia*, various *Eupatorieae*, *Tibouchina*, *Leandra*, and *Myrtaceae*) and short stunted trees (e.g. *Escallonia*, *Weinmannia*, *Rapanea*, *Symplocos*, *Maytenus*, *Roupala*) and bamboo (*Chusquea* spp.) with a sparse understory of herbs and pteridophytes. Common families are, in order, *Asteraceae*, *Polypodiaceae* sensu lato, *Melastomataceae*, *Orchidaceae*, *Poaceae*, *Lamiaceae*, *Lycopodiaceae*, *Cyperaceae*, *Ericaceae*, and *Rubiaceae* (Safford, 1999a,b).

In the lower Campos de altitude, close to treeline, the grasslands co-exist with azonal vegetation types such as stands of elfin or Araucaria forest, wetlands and peat bogs (Safford, 1999a,b). The modern vegetation structure is also shaped by anthropogenic fires and grazing (Safford, 1999a,b).

Floristic endemism is high; estimates range from 25%–33% endemic species (Iganci et al., 2011). These high numbers of endemics suggest that the vegetation is quite old, at least since the Late Pleistocene (Behling, 1997), and not solely the product of recent human disturbances. The vegetation shows strong floristic similarities to equatorial alpine formations of the Andean and Central American Cordillera despite aerial disjunctions (Safford, 1999a,b).

Ecosystem Services of Alpine Grasslands

The biodiversity and ecosystem functioning of alpine grasslands provides a multitude of ecosystem services that promote human wellbeing. These services include the provision of fresh surface water, food, fiber, fuel and genetic resources; regulating services such as pollination, seed dispersal, climate regulation; hazard and erosion control; and water purification. Moreover, grasslands support primary production, habitat provision, nutrient and water cycling and soil formation, as well as providing cultural services, such as education, recreation and spiritual values (Peart, 2008).

For example, the Páramos and the Puna are key in sustaining the lives of millions of people, by providing essential ecosystem services such as water for urban use, irrigation and hydropower generation. Moreover, the soils and vegetation promote carbon storage and sequestration (IUCN and WCPA, n.d.).

Grassland biodiversity, such as that of the Campos de altitude, safeguards these ecosystem services, but the impacts of climate change on biodiversity might negatively affect the ecological flows and ecosystem services that grasslands provide for human well-being (Díaz et al., 2015).

Conservation of Alpine Grasslands

Threats

Human use and disturbance

As opposed to other continents, human settlement and seats of political power in South America were historically concentrated in the mountains, with habitation by ancient peoples well before the establishment of the Inca Empire in the 15th Century (Mathieu, 2013). This long history of human occupation and use of the mountains has led to constant human encroachment and resulting threats to the alpine grassland environments.

Peart (2008) identified common threats to temperate grasslands of South America, which include the Páramos and Punas due to their elevated position and thus temperate resemblance. These threats include: 1. Livestock grazing, 2. Conversion/clearing for forest plantations and crop production, 3. Mining and energy production (precious metals, coal, oil/gas, and electricity), 4. Urban and infrastructural expansion, 5. Altered fire regimes, 6. Inadequate hydrological management, 7. Lack of protection of biological resources and poor management of protected areas, 8. Exploitation of species through collection for fuel and medicinal plants, illegal hunting/poaching.

Peart (2008) points out that these drivers of grassland change are modified by climate change and that the interplay of human encroachment with climate change might lead to structural landscape changes through habitat loss, fragmentation, loss of diversity and integrity degradation, and even desertification of temperate grasslands.

These general threats vary between the three grassland regions due to the different environmental biotic and abiotic conditions and due to differing human legacies, discussed below.

Páramos

The predominantly wet climatic conditions of the Páramos are unfavorable to livestock and agriculture, resulting in low human populations. Nonetheless, there are ancient Inca and pre-Inca roads, terraces and houses (Lægaard, 1992). Despite the low level of habitation, human influence is pervasive. Past human communities in the high Andes were generally characterized by self-sufficient subsistence farming due to isolation, combined with access to a broad resource base (Ramsay, 1992). During colonial times, mining penetrated the Páramos. In dry years, occasional burning takes place (Lægaard, 1992). However, extensive burning, cultivation, and grazing only began with the arrival of European settlers (Sarmiento, 1986). Burning has increased in recent times. The aim is to alter the nutritional value of the 'pajonal' tussocks, by removing choking dead leaves, thereby stimulating the growth of succulent new shoots (Ramsay, 1992).

Nowadays, dispersed stock raising, mining, and extraction of firewood and canes are taking place (Alba Mejía, 2008). Recently, the Páramos have been exposed to high levels of grazing (Molinillo and Monasterio, 1997), agricultural expansion and intensification (Suárez and Medina, 2001) resulting in high ecosystem degradation (Sarmiento, 2000). Shrubs are collected for fuel, resulting in overutilization and degradation of the ecosystem (Ramsay, 1992).

Overgrazing results in a decrease of species richness, changes in soil properties, an increase of bare surfaces, and the risk of water channeling and wind erosion (Podwojewski et al., 2002).

The Páramos are already susceptible to natural fragmentation due to the rugged topography and associated microclimates. The alpine location, coupled with the transitional climate between low and high areas, dry and wet, makes the Páramos highly vulnerable to climate change and desiccation, which interplays with fragmentation, deforestation, mining and other anthropogenic impacts (Alba Mejía, 2008). Moreover, wildlife hunting and killing by farmers across the Páramo has caused, and is still causing, faunal declines across all animal groups (Ramsay, 1992).

Punas

The Punas have experienced human influence for millennia, causing huge changes in the natural vegetation. Puna regions some of the most modified areas in Peru and Bolivia.

Human habitation is highest in the humid and eastern Punas. All of the Puna is grazed in some form or other by sheep, alpaca and llamas, with cattle, horses, donkeys and pigs disrupting the completion of life cycles for many plants, resulting in degradation (Alba Mejía, 2008).

The central Puna region is also cultivated with tubers and grains. The grazing regime undergoes seasonal patterns, with migration of the herds to the humid 'bofedales' during the dry season and grazing shifts to the extensive grasslands/shrublands during wetter seasons. Fire is used as a management tool to establish grazing areas. The combination of extensive grazing with fire threatens natural meadows, shrublands and woodlands, and particularly the edges of wetlands and moist habitats grazed in the dry season. Some Puna regions have also been strongly affected by mining, urban development and waste disposal (Alba Mejía, 2008).

Campos de altitude

The fate of the island-like Campos de altitude is strongly determined by the surrounding Atlantic Forest biome, which acts as a buffer to maintain local climate and avoid species invasions (Martinelli, 1989). Therefore, current deforestation and savannization of the Atlantic Forest biome will likely have negative effects on the Campos de altitude as well (Scarano et al., 2016).

Since large parts of the Campos de altitude are within protected areas, anthropogenic fires and grazing are mostly excluded. However, there is an evident increase in the frequency of fires, with largely unknown origin and causes (Aximoff and de Carvalho Rodrigues, 2011).

Climate change

Mountain ecosystems are especially vulnerable to climate change due to (1) the very specific adaptations and narrow niches of species, which mean that even small environmental changes can cause a re-assemblage of species communities and (2) the limited and small extent of mountain ecosystems and the tendency towards fragmentation, coupled with physical barriers hindering species migrations to and from other mountain ecosystems (Grabherr et al., 2003).

Much research has been conducted on how altitudinal vegetation and ecotones in mountains, and especially treelines, change with increased temperatures (Harsch et al., 2009; Malanson et al., 2011; Körner, 1998; Körner and Paulsen, 2004). The treeline is the transition zone between closed forest and alpine grasslands, and marks the lower boundary for alpine grassland ecosystems (Fadrique et al., 2018). Treeline shifts determine the potential areal extent of alpine grasslands.

There are generally two contrasting trends of altitudinal shifts of mountain ecosystems in response to global warming. As temperatures increase, species migrate upslope to match their thermal niches, or they shift downslope due to land-use legacies and anthropogenic suppression of tree growth (Feeley and Rehm, 2015). Upslope shifts have been witnessed across the world. Morueta-Holme et al. (2015) found an upslope migration of vegetation zones on the Ecuadorian Mount Chimborazo of up to 400 m since Alexander von Humboldt visited in 1805.

Fadrique et al. (2018) assessed the directional shifts of mountain forest ecosystems in the tropical Andes biodiversity hotspot and witnessed a process called thermophilization, i.e. the change in composition towards greater abundances of lowland species. However, the rates of compositional change are variable, due to different warming rates and varying community composition along ecotones, such as treelines (Fadrique et al., 2018). Beyond that, individual responses of plants will likely differ substantially (Löffler et al., 2011).

Upslope migration can be limited by low dispersal capabilities of alpine species, fragmentation, isolation and the lack of migration routes, so that in many cases, upwards movement lags behind temperature increases (Löffler et al., 2011). Extinctions of mountain-top species take place when their upslope migration is hindered by the physical lack of land at higher elevations. In the short term, warming experiments for mountain ecosystems reveal changes in plant growth and reproduction, phenology, vegetation structure and assemblage composition, while longer-term experiments show an increase in species homogeneity (Löffler et al., 2011).

Climate warming has the potential benefits for vegetation, such as the prolongation of the growing season, but these seeming advantages may well be overridden by negative effects on growth and reproduction caused by, for instance, increased frost damage or reduced snowpack (Inouye, 2008; Wipf et al., 2006). In the Páramos, upslope migration of treeline is reduced because of the difficulty of tree seedling establishment at high elevations caused by night frosts, fires and extreme radiation (Löffler et al., 2011).

The opposite trend of downslope shifts of vegetation zones and alpine ecotones can be caused by land use changes. For example, the high-elevation 'pajonal' grasslands of Mount Chimborazo expanded their distribution several hundred meters downslope, driven by forest clearing, cattle grazing and fire (Feeley and Rehm, 2015). A similar effect is known for treelines in the Andes. In areas used for cattle grazing and fires, treeline is much less likely to migrate upwards than in protected areas (Lutz et al., 2013).

Consequently, the alpine biota of South America is expected to undergo large ecological changes. In particular, the fauna will likely suffer from modifications in host-plant interactions, food availability, habitat quality and predator/parasite abundance (Löffler et al., 2011).

Climate Change Forecasts

Under the multitude of global change drivers, alpine grassland species will either adapt, move or go extinct (Hofstede et al., 2014). High Andean Tropical ecosystems are expected to face exceptionally strong warming effects and associated ecosystem changes during the 21st century because of their elevation (Bradley et al., 2006), as exemplified through projections for vertebrate species turnover rates of up to 90% for low to mid-high emission scenarios (Scarano et al., 2016).

However, responses of tropical mountain ecosystems to climate change will certainly be variable. Tovar et al. (2013) assessed Andean ecosystems under different climate scenarios and found that not all biomes move in the same direction and at the same degree, such that for 2050, 75–83% of biomes will stay stable, 4–8% will change significantly, and 13–17% do not show consensus in models.

The Páramos will most likely be affected by modifications in precipitation regime, relative humidity, and higher levels of solar radiation. In addition, changes in climate will drive the expansion of agriculture and livestock into higher elevations (Araújo and Rahbek, 2006; Hofstede et al., 2014). Cuesta-Camacho et al. (2008) estimate that around 35% of the 102 bird species and 60% of the assessed 125 plant species in the Páramos will either go extinct or become critically endangered until 2080. These scenarios of

species losses or threats are due mostly to the poor dispersal capabilities of alpine species. Moreover, climate change will impact Páramos' plant biodiversity through an increase in diseases and plagues, replacement through invasive species, and negative effects of increased radiation on plant structures (Hofstede et al., 2014). As vegetation belts move upwards under global warming, the Campos de altitude will experience a loss of available habitat, especially for plants (Spehn and Körner, 2005; Scarano et al., 2016).

Knowledge Gaps

Mountain ecosystems such as the Campos de altitude remain poorly studied, and there is a need to establish long-term ecological monitoring sites to track the effects of climate change on species and ecosystems (Scarano et al., 2016), especially since compositional change is not necessarily heterogenous across elevations (Fadrique et al., 2018).

With many studies focussing on forest ecosystems, the plasticity of grassland species in the face of increased temperatures and reduced humidity remains largely unstudied (Scarano et al., 2016). While most mountain climate change studies focus on shifts in vegetation zones, we know far too little about the responses of ecosystem functions like carbon sequestration and water provision. Ecosystem responses are multifaceted and include habitat reductions, species and population changes, alterations in phenology, plant-animal interactions, and trophic cascades. Furthermore, complex interactions complicate predictions on ecosystem changes for alpine grasslands (Scarano et al., 2016).

For the Páramos, central uncertainties include the lack of knowledge for species dispersal under different degrees of human alteration, the manner in which genetic diversity of populations respond to climate change, and how diversity generally will help in promoting adaptation (Fadrique et al., 2018; Hofstede et al., 2014).

Conservation Status

In comparison to large forest ecosystems such as the Amazon, alpine tropical grasslands are relatively neglected by conservationists and need to be recognized as valuable ecosystems and conservation units. The Campos de altitude, for instance, is not even represented within the Dinerstein et al. (2017) ecoregion framework.

In terms of raw numbers, the Páramos have a comparatively high proportion of protection of 43%, while only 18% of the Puna is protected (Michelson, 2008). However, high levels of protection must also be seen in the light of the simplicity of establishing protected areas in high and remote places, when there is little competition with human needs (Watson et al., 2014).

Recent years have seen the establishment of several international programs, such as the Alpine Convention (Austria), the Centre for Mountain studies (UK) and the International Mountain Society (Switzerland), concerned with the evaluation and protection of mountain biodiversity. However, most of the programs focus on mountain ecosystems of Europe, North America and Asia (Martinelli, 2007). Recently, organizations like the Temperate Grasslands Conservation Initiative, which included the Páramos and Puna, have been created to serve as the centre point for international communications and collaboration for the improved conservation and protection of the world's indigenous temperate grasslands. Despite the existence of conservation initiatives, on the ground implementation of alpine grassland conservation still falls short. In the Puna, for instance, a major problem is the lack of management effectiveness in protected areas, and the low representation of the wet Puna ecoregion, where only 6% of the ecosystem is protected (IUCN and WCPA, n.d.).

The relatively tiny Campos de altitude cover 350 m² on four disjunct mountain ranges, and are, to a large degree, part of some of the oldest protected areas of Latin America, yet until recently, management plans were non-existent or not enforced (Safford, 1999a,b). The largest remnants of the Campos de altitude are found in Itatiaia National Park, with 50 km² on the Itatiaia Plateau. Despite the protection of the Campos de altitude in four national parks, large distances of 50–150 km between the protected areas are a serious problem for species migration (Safford, 1999a,b). On top of that, most protected areas either lack specific conservation and management plans or the policies fail to account of the peculiarities of mountain environments, resulting in degradation even within the protected area boundaries. Thus, conservation planning must consider the distinct communities and biotic zones, particularly in regard to elevation (Martinelli, 2007).

Conclusion

The high levels of biodiversity, endemism, evolutionary significance and unique species assemblages make the South American alpine grasslands some of the most diverse and valuable ecosystems worldwide. The mountaintop grasslands serve as relict places and refugia for highland species and also provide a multitude of ecosystem services, thus meriting protection from an eco-centric and anthropocentric point of view.

Alpine grasslands are facing multidimensional threats, especially degradation, climate change and insufficient protection and management. Many of the threats are interlinked and have to be understood holistically, from an ecosystem perspective, to scrutinize how environmental change will affect the biosphere, hydrosphere, pedosphere and cryosphere of the alpine grasslands.

Historically, the ecology of grasslands has mostly been neglected and overlooked. Nowadays, in the light of growing environmental pressures, there is an essential need to recognize grasslands as valuable ecosystems in their own right to guarantee maximum protection, such as by including them into ecosystem/biome categorizations and by embedding grassland restoration and protection into carbon-sequestration programs like REDD.

Ultimately, any restoration proposals and protection measures should account for the unique ecology of alpine grasslands and be adaptive to fast-changing environmental drivers, in order to guarantee the continued existence of those unique ecosystems.

Abstract

Volcanic episodes linked to the East African Rift System gave rise to the Ethiopian highlands and most of the isolated mountain peaks in Kenya, Tanzania and Uganda, collectively referred to as the Afroalpine region. These highly disjunct high elevation enclaves or “sky islands” (3500–4500 m a.s.l.) are thought to have been colonized by plant taxa during the Plio-Pleistocene whose distributions expanded further during dry cycles in the Holocene. Phylogeographic studies suggest mostly a northern hemisphere origin from Holarctic ancestors. This Afroalpine region is recognized as a regional center of plant endemism with c. 81% of its plant species and four plant genera found nowhere else in the world. It is generally species-poor with no more than 300–680 vascular plant taxa recorded across the various mountains. It has an estimated total area of 3500–5000 km² linked exclusively to the alpine belt. The major Afroalpine vegetation types are open *Dendrosenecio* woodland, Afroalpine scrub, *Carex* and *Scirpus*-dominated bogs, and tussock-forming temperate grasslands. The most iconic plants of the Afroalpine region are the giant life-forms of *Lobelia* and *Dendrosenecio*, well adapted to strong diurnal-nocturnal temperature ranges repeated throughout the year. Levels of protection vary from mountain to mountain and from country to country, whilst anthropogenic pressures are high, mostly due to heavy grazing pressure from livestock farming and regular fire.

Introduction

Volcanic episodes linked to the East African Rift System, culminating in the Eastern and Western Rift branches, gave rise to the highlands of Ethiopia and most of the isolated mountain peaks in Kenya, Tanzania, and Uganda during the Miocene to late Pliocene (Baker et al., 1972; Griffiths, 1993). These highly disjunct enclaves or “sky islands” are scattered throughout equatorial eastern and north-eastern African mountains (Fig. 1) between latitudes 14°N and 6°S, and longitudes 25°E and 40°E (Hedberg, 1994; Wesche et al., 2008a). Together they comprise what has been termed the “Afroalpine” region, named in part after the global “alpine” concept—pre-Indo-Germanic for “steep slopes” or “high mountains” (Körner et al., 2006)—which reached Africa by the 19th century (e.g., Engler, 1892, 1904). By no means, however, was a systematic relationship with the alpine flora of the European Alps implied (Killick, 1963; Herbst and Roberts, 1974). Hauman (1933, 1955) added the prefix “afro” to assert an African context, a tradition reinforced by Monod (1957) and Hedberg (1961, 1964) amidst criticism by others (e.g., Boughey, 1955).

Flora and Vegetation

“Flora” refers to the plant species composition of a particular region or habitat, listed according to a taxonomic hierarchy. “Vegetation” is a broader term, referring to the particular assemblages of plants in a particular region or habitat grouped by their general structural appearance. Studies relating to vegetation zonation—the natural “layering”/stratification of vegetation communities along an elevation gradient—have had a major bearing on understanding the vegetation of the Afroalpine region. The vegetation of the broader tropical African highlands is partitioned into alpine, ericaceous subalpine scrub-forest and montane forest belts, the latter capped with stands of bamboo and *Hagenia-Hypericum* (Hedberg, 1951, 1955). The zonation studies not only relate to the partitioning of distinctive vegetation belts within a landscape (e.g., Richards, 1963; Hall, 1973; Bussmann, 2006), but also relate to elevational zonation gradients within a single vegetation type such as forest (e.g., Hamilton and Perrott, 1981; Hemp, 2006a). These vegetation belts are more sharply delineated than the high elevation vegetation of southern Africa (Hedberg, 1997), probably due to steeper altitudinal gradients in the Afrotropics. However, during the Last Glacial Maximum (LGM), much of Africa’s high mountains were glaciated and vegetation belts descended to lower elevations by as much as 1000 m (Coetzee, 1964; Bonnefille

Fig. 1 Approximate location of the Afroalpine “sky islands” in tropical Africa, stretching from the Simen Mtns in northern Ethiopia to Mt. Hanang in Tanzania. Mt. Cameroon in West African is an active volcano and therefore not well representative of the Afroalpine region. Africa’s only other alpine system is located further south in the Drakensberg Mountain Centre. Adapted from Carbutt, C. and Edwards, T. J. (2015). Reconciling ecological and phytogeographical spatial boundaries to clarify the limits of the montane and alpine regions of sub-Saharan Africa. *South African Journal of Botany* **98**, 64–75, with permission.

and Riollot, 1988; Olago, 2001). The Afroalpine region therefore occupied a considerably larger area during the LGM when the climate was cooler and drier (Ehrlich et al., 2007), estimated by Chala et al. (2017) at eight times greater than at present. During the LGM, most of the Afroalpine enclaves of the Ethiopian highlands were interconnected except across the Great Rift Valley whereas the alpine habitats on isolated mountains of East Africa remained disconnected (Chala et al., 2017).

Strictly speaking, the Afroalpine flora and vegetation is restricted to the alpine belt, essentially the area above the upper treeline ecotone of the ericaceous belt, ranging from a lower limit of 3550–4100 m a.s.l. to an upper limit of 4500 m a.s.l. where continuous vegetation cover is absent (Wesche et al., 2008a; Gehrke and Linder, 2014). Kiage and Liu (2006) erroneously placed the alpine belt below the ericaceous belt. The alpine belt in tropical Africa has an estimated total area of 3500–5000 km² (Hedberg, 1994; Gehrke and Linder, 2014). The Afroalpine flora is generally species-poor, comprising no more than some 300–350 vascular plant species (Hedberg, 1994), although a more ancient African volcano such as Mount Elgon has a comparatively richer flora (680 vascular plant species) (Wesche, 2002). The major Afroalpine vegetation types are open *Dendrosenecio* woodland, Afroalpine (*Alchemilla* and *Helichrysum*) scrub, *Carex* and *Scirpus*-dominated bogs, and tussock-forming temperate grasslands dominated by the grass genera *Avena*, *Festuca*, *Koeleria*, and *Poa* (Hedberg, 1994; Wesche et al., 2008a). No doubt the most iconic plants of the Afroalpine region are the giant life-forms of *Lobelia* (Fig. 2) and *Dendrosenecio*, the latter referred to as “giant groundsels” (Hedberg, 1994). The alpine belt is regarded as treeless despite the unorthodox occurrence of these taxa—they rarely aggregate in dense concentrations and are sometimes regarded as giant herbs rather than trees. The closely affiliated upper-montane (subalpine) communities include ericaceous scrub dominated by *Cliffortia*, *Erica*, *Hypericum* and *Stoebe*, and grasslands dominated by *Andropogon*, *Exothea*, and *Sporobolus* (Hedberg, 1964; Wesche et al., 2008a). Knapp (1973) showed a clear distinction between upper-montane and alpine grasslands. Grimshaw (2001) proposed combining the alpine and ericaceous belts to form the “altimontane” belt but the inclusion of the term “montane” is contradictory in this context, given the conceptual inclusion of the alpine belt.

Wesche et al. (2008a) gave an overview of detailed vegetation surveys of the larger northern Rift Mountains spanning the last two decades, but noted knowledge gaps from the Albertine Rift and Ethiopia, and from a vegetation type perspective, knowledge of the

temperate grasslands above the treeline is limited. The majority of Ethiopian alpine vegetation studies have focused on the Great Rift escarpment of northern Ethiopia (Aynekulu et al., 2012) and the Bale Mountains towards the south (Assefa et al., 2011; Tallents and Macdonald, 2011). The latter region contains the largest and most intact expanse of Afroalpine vegetation on the Sanetti Plateau (Fig. 2) (Yalden, 1983; Brooks et al., 2004).

Fig. 2 Typical Afroalpine landscapes and vegetation: (A and B). The most expansive area of Afroalpine vegetation occurs on the Sanetti Plateau, Bale Highlands, Ethiopia; (C and D). One of the iconic giant life-forms of *Lobelia*, *L. rhynchoptalum*. Adapted from Carbutt, C. and Edwards, T.J. (2015). Reconciling ecological and phytogeographical spatial boundaries to clarify the limits of the montane and alpine regions of sub-Saharan Africa. *South African Journal of Botany* **98**, 64–75, with permission.

High Elevation Treeline

The correct partitioning of the Afroalpine region from the closely associated lower-lying Afromontane region (and associated flora and vegetation) hinges in part on the explicit understanding that the “treeline” is a thermal boundary separating the alpine and montane belts (Körner et al., 2011; Körner, 2012). The treeline (or treeline ecotone) in tropical Africa occurs between 3550–4100 m a.s.l. (Hedberg, 1951; Jacob et al., 2014), grading into alpine scrub at higher elevations and montane forest at lower elevations. This treeline is essentially the upper extent of the ericaceous belt (Hedberg, 1951; Wesche et al., 2000), comprising dense stands of shrubs or small trees such as *Erica arborea* and *E. trimera* (Hedberg, 1997; Gizaw et al., 2013), although small groves of both species also occur as outposts in Afroalpine grasslands (Wesche et al., 2000). The most well developed and intact ericaceous belt is located in the Rwenzori Mountains, most likely because it is an exceptionally high rainfall region (Wesche et al., 2000). The ericaceous belt is the best placement for the treeline in tropical Africa given Körner’s (2003, 2012) definition of the natural upper-climatic treeline includes the uppermost pockets of trees above the forest line. This treeline is not always easy discernable as it can grade seamlessly into montane forest, and is a dynamic boundary that expands and contracts depending on the prevailing environmental conditions. Therefore, the “climate-elevation,” or more recently the “isothermal” control model of treelines (Körner, 2003, 2012), must also be tempered with smaller-scale disturbance drivers in the Afrotropics such as regular dry season fire and grazing (Wesche et al., 2000; Fetene et al., 2006; Wesche, 2006), as well as climate change and associated warming and drying events (Hemp, 2005). The harsh soil surface microclimate at the alpine-treeline boundary is thought to limit seed recruitment of treeline-forming species (Wesche et al., 2008b). Fire and anthropo-zoogenic impacts (especially burning practices to remove woody vegetation for livestock grazing) are believed to stabilize the treeline, preventing treeline advancement to higher elevations predicted to occur as a result of climate change (Jacob et al., 2014; Johansson and Granström, 2014).

Climate-Induced Adaptive Ecophysiology

The climate of the high elevation Afrotropics is characterized by significant daily temperature oscillations that occur throughout the year (Hedberg, 1964; Sarmiento, 1986; Fetene et al., 1998). For example, in the Rwenzori Mountains, daily temperatures range between -5°C and 20°C over a 24 h period in the alpine and nival zones (Eggermont et al., 2009). These ecological constraints are reflected in adaptive syndromes such as the giant life-forms of *Lobelia* (Fig. 2) and *Dendrosenecio* (Hedberg, 1964; Mabblerley, 1986). Such Afroalpine plant life forms are convergent with *Espeletia* and *Puya* in the Andean Páramo where similar conditions prevail (Meinzer and Goldstein, 1986; Ramsay, 2014). Pachycaulous (thick-stemmed) architecture, incorporating large caulescent leaf rosettes (a radiating arrangement of spreading leaves supported by an above-ground stem) that protect the developing shoot apex, and marcescent leaves (dead leaves remaining on the stem after they senesce) which insulate the stem, are believed to limit cold injury when night-time temperatures drop well below freezing (Hedberg, 1964; Meinzer and Goldstein, 1986; Fetene et al., 1998). Warm daytime temperatures probably release adequate soil nutrients to sustain these large plants (Hedberg, 1964).

Socio-Ecological Drivers

The major vegetation types constituting the alpine (and upper-montane) communities are subject to seral changes under different fire and grazing regimes (Johansson and Granström, 2014), with grasslands usually replacing woody vegetation under high fire frequency and intensity due to periodic droughts every 7–10 years (Hemp, 2006b; Wesche, 2006; Abera and Kinahan, 2011). Periodic droughts also result in desiccation stress and are thought to impact seedling establishment (Wesche, 2003). Such disturbances from fire disrupt competitive dominance and increase available habitat for less competitive alpine plants, thereby preventing treeline ascent and increasing the Afroalpine flora’s resilience to global warming (Johansson et al., 2018). Human impacts on Afroalpine vegetation during the Holocene may have been relatively minor (Umer et al., 2007), although Nyssen et al. (2004) suggest anthropogenic impacts dating back to at least 5000–4800 years BP. More dramatic changes have been detected over the past 40 years (Kidane et al., 2012). The United Nations Reducing Emissions from Deforestation and Forest Degradation (REDD⁺) program (e.g., Watson et al., 2013), which incentivizes developing countries to keep their forests standing, is believed to be a threat to traditional fire management practices in the Afroalpine region because it aims to increase carbon storage through fire suppression (Johansson et al., 2018).

Phytogeography and Endemism

The Afroalpine region is recognized as a regional center of plant endemism with c. 81% of its plant species and four plant genera found nowhere else in the world (Hedberg, 1961, 1964). Not only is this home to a unique assemblage of plant life. A number of animal species, such as the Big-headed African Mole-rat (*Tachyoryctes macrocephalus*), Blue-winged Goose (*Cyanochen cyanoptera*), Ethiopian Highland or Starck’s Hare (*Lepus starcki*), Ethiopian Wolf (*Canis simensis*), Gelada (*Theropithecus gelada*), and Walia Ibex (*Capra waliae*) are largely endemic to this unique ecosystem (Wesche et al., 2008a; Sillero-Zubiri et al., 2011). The evolution of endemics is attributed to steady adaptive responses to the environment (Hedberg, 1964, 1986) characterized by periods of

Table 1 Breakdown of the phytogeographical elements highlighting the complex derivation of the Afroalpine flora of tropical Africa. More recent studies suggest a greater affiliation with the temperate floras of the Northern Hemisphere

Element	Number of taxa	Percentage of total (%)
Pantemperate (subcosmopolitan)	87	33
Endemic Afromontane ^a	82	32
Northern Hemisphere (Boreal)	34	13
Southern African ^b	25	10
Mediterranean	18	7
Himalayan (Siwalik)	8	3
Southern Hemisphere	6	2
Σ	260	100

^aEndemic Afromontane element includes the endemic Afroalpine element.

^bSouthern African element comprises the South African and Cape elements.

Adapted from Hedberg, O. (1961). The phytogeographical position of the Afroalpine flora. *Recent Advances in Botany* **1**, 914–919; Hedberg, O. (1965). Afroalpine flora elements. *Webbia* **19**, 519–529. Used from Carbutt, C. and Edwards, T. J. (2015). Reconciling ecological and phytogeographical spatial boundaries to clarify the limits of the montane and alpine regions of sub-Saharan Africa. *South African Journal of Botany* **98**, 64–75, with permission.

isolation from other high mountain temperate biotas (Hedberg, 1969) and persistence in isolated small refugia during glacial cycles (Gizaw et al., 2013; Masao et al., 2013). This has resulted in low levels of genetic diversity and bottlenecks (Masao et al., 2013) followed by alternating stochastic episodes of intermountain gene flow (Wondimu et al., 2014). The nonendemic element of the Afroalpine flora appears more closely affiliated with the temperate floras of the Northern Hemisphere than the flora of its adjacent lowlands or of the Southern Hemisphere (Table 1). It is therefore regarded by Linder (2014) as a “northern temperate flora.” Collectively, its “Tropic-alpine” flora is regarded as Africa’s youngest (Linder, 2014) and is thought to have colonized the Afroalpine region during the Plio-Pleistocene (Gehrke and Linder, 2014) and expanded during dry cycles in the Holocene (4500 years BP; Umer et al., 2007). Although elements of the Afroalpine flora are relatively recent colonizers (e.g., Gizaw et al., 2013; Wondimu et al., 2017), the actual time of colonization and mechanisms of speciation remain poorly understood (Gizaw, 2012). Other elements are believed to be Tertiary relicts (e.g., Gizaw, 2012).

Several Afroalpine species colonized Africa from Asia during the Pleistocene via the coastal mountain ranges of the Arabian Peninsula (Koch et al., 2006; Eggermont et al., 2009). One proposal is that the African mountains were almost devoid of vegetation above the treeline until land contact was established between the African and European plates in the Middle Miocene about 18 Ma BP, and again in 13 Ma BP, facilitating the migration of temperate plant genera into Africa’s high elevation regions (Eggermont et al., 2009). A number of other taxa entered Africa from this northern track. Examples derived from Holarctic ancestors include *Trifolium* (Ellison et al., 2006), *Arabis alpina* (Koch et al., 2006), *Cardamine* (Carlsen et al., 2007), *Lychnis* (Popp et al., 2008), *Alchemilla*, *Carex*, and *Ranunculus* (Gehrke and Linder, 2009), *Dianthus* (Valente et al., 2010), and *Scabiosa* (Carlson et al., 2012). Thus repetitive episodes of immigration from the Northern Hemisphere, in combination with in situ radiation, have heavily influenced the composition of the high elevation floras of sub-Saharan Africa, making the Holarctic the most important source of lineage recruitment (McGuire and Kron, 2005; Gehrke and Linder, 2009; Eggermont et al., 2009). A lesser but still significant influence is a southern or “Cape” origin with clades such as *Disa*, *Irideae* p.p., *Moraea*, *Passerina*, *Pentastichis*, and *Restionaceae* migrating northwards along mountain corridors into tropical Africa. This southern track is thought to have facilitated at least 18 unidirectional radiation events (Linder, 2003; Galley and Linder, 2006; Gehrke and Linder, 2009). A wide range of phylogenetic patterns suggest highly individualistic responses to Pleistocene climatic oscillations and therefore different phylogeographic histories (Masao et al., 2013).

Conclusion

Finding a home for the placement of the Afroalpine flora in African phytogeography has been an ongoing dilemma. White (1978) included it in the broader Afromontane phytochorion (a phytochorion, in phytogeography, is a geographic area with a relatively uniform composition of plant species). White’s (1978) delineation of the Afromontane phytochorion should rather, however, only reflect the distribution of a montane flora and vegetation linked to the montane belt located below the treeline (Carbutt and Edwards, 2015), and which is more closely related to lowland forests (Hedberg, 1994; Linder, 2014). This would then, correctly, exclude the alpine belt of the Afroalpine region characterized by a distinct assemblage of plant (and animal) taxa in terms of life-forms, species composition and high species endemism (Hedberg, 1961) and having unique extra-African affinities (Linder, 2014). The historical inclusion of the Afroalpine region as part of the broader Afromontane framework (e.g., White, 1978) therefore reflects the lack of alignment between the phytogeographical and ecological contexts of this phytochorion (Carbutt and Edwards, 2015). When the Afroalpine flora is included as part of the “endemic Afromontane element,” levels of endemism change significantly from 81% to 32% (Table 1) due to the incorporation of a larger number of Afromontane species in a larger floristic region with disproportionately fewer endemics.

Final Thoughts

Africa's only other alpine system, located in the Drakensberg Mountain Center in southern Africa (Carbutt and Edwards, 2015), is also characterized by numerous endemic plants (Carbutt and Edwards, 2006). Unfortunately in the past it has also been referred to as "Afroalpine" (e.g., Killick, 1978) but this attribution fails on both floristic and ecological grounds (Carbutt and Edwards, 2015). Another misapplied term is "tundra" (e.g., Killick, 1997), a term that should not be applied to alpine environments (Körner, 2001, 2003), including those of tropical and southern Africa. Although there are various types of tundra, the term is most commonly associated with the Arctic and Antarctic regions characterized by subsoil permafrost. The Afroalpine landscape has also been referred to as "moorland" (e.g., Mekonnen et al., 2011), which generally refers to upland areas of open, uncultivated land dominated by heather on acidic soils, or "steppe" (e.g., Sillero-Zubiri et al., 2011), more generally applied to the extensive tree-less landscapes of Eurasia.

Much of the Afroalpine region is under various forms of formal protection, ranging from 30% in Ethiopia to almost 100% in East Africa (Wesche et al., 2008a). Few of these areas, however, are free from human impact. Poaching, poverty, political instability, high livestock grazing pressure, lack of security, limited budgets and regular anthropogenic fires all pose significant challenges, although fires do maintain grassland diversity and vegetation mosaics (Wesche et al., 2008a; Johansson and Granström, 2014). One hopes that this biologically and culturally diverse and unique region will receive more attention from conservationists, politicians, and researchers.

Abstract

The Asian tropics are a zone of plate collision that has led to relatively young mountains across the region. Surprisingly, the highest areas where above-treeline habitats are found are all on islands rather than mainland tropical Asia. Isolated ranges in Taiwan and Borneo have a few peaks reaching 4000 m while there are extensive areas on 50 peaks above this elevation in Papua (Indonesia) and Papua New Guinea. The Taiwanese mountains experience seasonal weather, but the equatorial mountains have mild rainfall seasonality and stable temperatures. Depending on rock type and steepness, above-treeline shrublands and grasslands occur above ca. 3700 m with the highest tree lines occurring on limestone around 4100 m elevation. The generally wet and cloudy environments limit temperature variations and lead to widespread organic soils and mire communities. Disturbance is limited as agriculture is not possible but currently some areas are exposed to increasing tourism and erosion.

Introduction

Tropical Asia is an active plate collision zone between the northward-drifting Australian plate and plates in the Pacific and Asian mainland. The area is accordingly mountainous and structured by shear zones and volcanism. The mainland south of the Tropic of Cancer (23.5°N) has many widely separated ranges (Table 1) but the summits lie at or below near 3000 m so are forested to their summits, except where the vegetation has been disturbed.

True alpine environments, with an estimated extent of around 3375 km², are only found on some high tropical mountains that occur on the islands lying between the continents of Asia and Australia, including central Taiwan, the Malaysian portion of the island of Borneo, the Indonesian archipelago and the island of New Guinea (both Papua New Guinea and Papua province, Indonesia) (Prentice et al., 2011). The highest point in this region is Puncak Jaya (Mt Carstensz) (4954 m) in New Guinea (Papua or Irian Jaya, Indonesia). This is the highest mountain on any island in the world. Significant peaks on other islands include the schist mountain Yushan (3952 m) in central Taiwan, the granitic Mount Kinabalu (4101 m) on Borneo and several peaks in Sumatra, Java, Lombok, and Sulawesi which exceed 3400 m. (Fig. 1 and Table 2).

The only extensive alpine habitats in the Asian tropics lie just south of the equator and extend for 1200 km along the island of New Guinea (Prentice et al., 2011; Hope, 2014). The New Guinea high mountains cover a latitudinal range from about 3°S to 8°S, with lower outliers to the west in the Bird's Head peninsula and to the east in New Britain. Fifty peaks exceed 3750 m and the area above 3600 m is 3350 km² (Hope, 2014) (Fig. 2). (Wikipedia:https://en.wikipedia.org/wiki/List_of_highest_mountains_of_New_Guinea).

Alpine Environments in the Asian Tropics

The true alpine biome is a zone above the climatic treeline, which, in the equatorial areas, correlates with a mean annual temp of 7.1 °C according to Körner (2012). Above the alpine is a nival zone, now restricted to Mt. Jaya and rapidly disappearing (Prentice and Hope, 2007). Summits are places with extreme conditions such as rock substrates, high exposure and rapid temperature changes so that, on isolated summits, treelines are often pushed down below the regional treeline elevation, reflecting local alpine conditions. In the Asian tropics the treeless zone includes low heaths, grasslands with scattered emergent shrubs, herb fields, mires and a variety of scree and cliff specialist vegetation.

Climate: The Asian tropical mountains are probably the most humid on Earth, surrounded by warm seas that are a major source of latent heat. Only the Amazonian slopes of the eastern Andes can match this level of humidity, and there is a substantial surplus of precipitation over evaporation in the summit areas, in contrast to African mountains such as Mount Kenya or those in the Trade wind belt such as Mauna Kea, Hawai'i. Yushan in Taiwan has seasonal cold temperatures, with a reliable snow cover from December

Table 1 Tropical mountains on mainland Asia.

Country	Peak	Summit elevation m	Latitude N
India (Kerala)	Anamudi (Ghats)	2695	10° 8.1'
Sri Lanka (Central)	Pidurutalagala	2524	6° 59.8
Myanmar (Chin)	Nat Ma Taung	3070	21° 11.9'

Indonesia (Sulawesi)	Rantemario/Latimojong	3478	3°23'06"S 120°01'27"E

to March, but the other alpine areas are equatorial so have constant insolation and reliable rainfall with few moisture deficit months (Fig. 3).

The central ranges of New Guinea intercept the southeast trade winds as well as monsoonal (Intertropical Convergence Zone) moisture from the north. The high rainfall convergence zone is > 1200 km north-south in the western Pacific and it usually overlies at least northern New Guinea throughout the year. Unlike Trade wind systems which are only 2–3000 m deep, the ICTZ is sufficiently deep to affect all Asian mountains. Thus, there are no extreme aspect or altitudinal differences in precipitation, in contrast to the rain shadow effects seen in the equatorial Andes or Hawai'i. In New Guinea, there is a pronounced precipitation maximum at mid- elevations (Prentice and Hope, 2007). However, rainfall totals there are so high (6000–12,000 mm per annum), and diurnal convective activity so intense, that any reduction in rainfall with elevation does not lead to moisture deficits longer than a few days at the summits in most years. Summit rainfall is estimated at ca. 2500–4000 mm pa for the main cordillera but is possibly less along the Owen Stanley Range in eastern PNG (around 8°S). Cloud-lie from mid-morning is a feature of most summit areas. Radiation levels under cloud have been shown to be quite low. Photosynthesis requires a minimum amount of solar radiation, and

Fig. 2 High elevation areas in New Guinea.

Fig. 3 Glaciers above the alpine in the Meren Valley Mt. Jaya. This photo was taken in 1972 and almost all ice in this photo has since melted.

adaptations by reptiles to overcome low ambient temperatures such as sun-basking will be of little use under cloudy conditions (Green and Stein, 2015). Pindaunde on Mount Wilhelm receives < 25% of the possible hours of sunshine because of almost permanent cloud cover (Hnatiuk et al., 1976) and in the same area alpine plants receive only one-third of the solar radiation of plants in the lowlands (Körner, 2012). This results in higher growing temperatures and more insolation on eastern slopes that experience morning sun than on western slopes or shaded areas, which may explain some vegetation patterning (Smith, 1977). The treeline lies at about the 7.1 °C mean annual temperature for all tropical sites (Körner, 2012).

There are a variety of seasonal precipitation maxima, and in eastern New Guinea a distinctly drier season of 2–3 months occurs from June–September. The very wet conditions reduce the diurnal temperature range by comparison with less humid areas of the Andes and Africa. Hence there is no analogue in this region to the “Afro-alpine” or Páramo zone where there are plant adaptations to severe frost.

However, El Niño events can lead to drought periods of several weeks’ duration every few decades, as occurred in 1972, 1984, 1997–98 and 2003. Kitayama (1996) notes the occurrence of air subsidence and extensive aridity associated with El Niño episodes in the alpine zone of Mount Kinabalu. He points out that high elevations of tropical mountains may be more sensitive to drought

than temperate mountains due to high diffusion coefficients and a high radiation load (Leuschner, 2000). In New Guinea, during El Niño droughts, heavy frosts caused tree deaths in the upper montane forest and crop losses down to 1500 m (Ballard, 2000).

While ground frost occurs on a high proportion of nights above 3750 m, temperatures below -5°C are rarely encountered. Surface temperatures in the intense sunlight can often exceed 30°C for a few hours in the morning. Between-year variability can be more extreme than within-year variation, which for Mount Wilhelm is the lowest so far reported of any of the tropical mountains (Körner, 2012: p. 45).

Wind is not a major factor in the tropics although locations on the mountains can be subject to high windiness due to funneling of katabatic flows. Typical wind pruning of heaths and better development of shrubs behind obstacles can occur but feldmark (severely restricted plant growth) is very rare.

Edaphic controls: Soils of the alpine range from extensive bare rock and screes, moraines and till sheets (lithosols) to deep clays and peats. Mt. Kinabalu has striking granite sheets exposed by unloading and vegetation is highly restricted by this (Fig. 4).

The underlying geology influences the formation of soil and growing conditions. For example, treeline woody vegetation reaches higher elevations on limestone than on impervious substrates such as basalt. This appears to reflect better drainage as most alpine soils are wet and prone to waterlogging. Glacial action also creates larger moraines and till sheets on some types of rocks which provide habitat for seedling establishment. On all substrates, organic debris and moss and lichen mounds develop into peat soils which are resistant to erosion by rain that sluices the rocky slopes. Peats are generally acidic and prone to waterlogging. Recent morainal debris formed by limestone gravels has a pH of 8.5 and is free-draining. This develops moss mats within 15–20 years that have pH levels of 4.5 and present new plant colonization sites (Hope, 1976; Fig. 5).

Disturbance: The alpine zone experiences numerous freeze-thaw cycles throughout the year and needle ice commonly disturbs exposed soils. Natural fires are rare but in frequently visited areas human-lit fires are widespread and can affect closed shrublands and grasslands. These are especially marked during El Niño drought episodes and fragment the treeline, for example at Mt. Giluwe, PNG. On longer timescales, frequent earthquakes destabilize slopes and many mountains were affected by neoglaciation (Little Ice Age) which increased snow lie and expanded glaciers between 1650 and 1850. Ice and snow retreat over the past century has exposed fresh ground that supports successional open herb or moss dominated communities despite minimal soil development.

Volcanic activity strongly limits ecological succession and the combination of loose ejecta and ground frosts make it very difficult for plants to colonize. Mt. Kerinci is an active volcano that has an extremely bare summit zone for these reasons (Ohsawa et al., 1985) (Fig. 6).

Main Vegetation Communities Above Treeline

The tropical Asian alpine vegetation communities are low shrublands and grasslands on medium to deep well-drained soils, open dwarf shrublands on shallow stony soils and several mire communities, including fens and moss and graminoid-dominated herb fields. The vegetation of the Taiwanese mountains differs from the mountains to the south and west because the flora is derived from China and lacks the strong Australian-sub Antarctic element found on the more equatorial islands. However, the main vegetation communities are similar structurally although wetlands are absent from the steep summit area.

Fig. 4 Granite summit plateau of Mt. Kinabalu, Malaysia.

Fig. 5 Dwarf shrub heath and open moss heath at 4400 m in the Meren Valley on Mt. Jaya. The mosses and scattered *Epilobium* tufts occupy a very young moraine while the shrubs lie outside the recent ice margin.

Fig. 6 Summit area of Mt. Kerinci, consisting of recent ash and debris from the crater.

The upper limit of the subalpine forest is generally a low dense forest formed by gymnosperms (in New Guinea podocarps such as *Dacrycarpus compactus*, on Kinabalu by *Dacrycarpus kinabaluensis* and *Phyllocladus hypophyllus* and on Yushan by the conifer *Abies kawakami*). Tree rhododendrons and other trees such as *Rapanea* (Mysinaceae), *Quintinia* (Paracryphiaceae) or *Schima* (Theaceae) often contribute. Isolated trees or patches of forest may extend above the forest limit, often as small stands of tall shrubland in sheltered places.

Heath and Open Dwarf Shrublands

The alpine climate inhibits woody plant growth (Körner, 2003). Shrubs are often low to the ground and set into graminoid communities. Heaths made of larger shrubs often reflect edaphic controls that limit tree growth, as on Mt. Kinabalu above 3300 m where soils are shallow or absent (Kitayama, 1992; Wong and Chan, 2015) (Fig. 7).

Fig. 7 Xeromorphic scrub vegetation at 3300 m on Mount Kinabalu. The shrubland is dominated by species with leptophyll leaves (up to 25 mm² in size) such as *Leptospermum recurvum*, *Rhododendron ericoides*, *Styphelia suaveolens* and *Gaultheria* species, with *Carex* and *Belvisia* species on rocky patches.

In New Guinea, alpine shrublands similar to the Kinabalu heath community grow to 0.7–1.5 m in height, and are dominated by *Coprosma* species such as *C. brassii* and *C. novoguineensis* with *Styphelia suaveolens*, various *Rhododendron* species (e.g., *R. versteegii*, *R. gaultherifolium*, *R. womersleyi*) and *Tasmannia piperita*. These tall heaths do not reach the highest elevation but exceed 4000 m on Mt. Jaya (Hope, 1976, 1980; Johns et al., 2006). On Yushan a tall heath of *Juniperus squamata* and *J. formosum* occupies the deeper soils.

At higher elevations, shrubs contribute to a formation called Dwarf Shrub Heath by Wade and McVean (1969). Small rounded shrubs of *Styphelia suaveolens*, *Trochocarpa decockii*, *Drapetes ericoides*, several species of *Tetramolopium* and of *Parahebe* occur on deeper, well drained soils interspersed with mosses and grasses.

The formation has variable floristics across the isolated peaks of New Guinea. Species that are prominent on one mountain are absent or rare on others. For example, the blue-flowered *Veronica tubata* (Plantaginaceae) is known from the Saruwaget Range and Mt. Wilhelm, while the alpine fern *Polystichum* (*Papuapteris*) *lineare* occurs on Mt. Albert Edward, Mt. Wilhelm and Mt. Giluwe (Hope, 2014).

On more exposed and higher slopes, a very open heath occurs with a carpet of mosses such as *Rhacomitrium* and *Campylopus* spp. and low (< 30 cm) small shrubs of *Tetramolopium* spp. and grasses such as *Poa nivicola* (Mangen, 1993). Small herbs such as *Cerastium papuanum* and *Epilobium detznerianum* grow in the moss cushions. Plant growth is excluded on bare ground, because the bare gravels are strongly frost-heaved.

The summit plateau of Mt. Kinabalu (Fig. 4) is largely bare rock, but small shrubs of *Rhododendron ericoides*, *Styphelia suaveolens*, and *Leptospermum recurvum* with sedges such as *Oreobolus ambiguus* and *Centrolepis philippinensis* and tussocks of *Deschampsia flexuosa* grow in crevices so a form of dwarf heath is probably present there, termed *Styphelia suaveolens*—*Trigonotis borneensis* heath by Smith (1980). Numerous species are shared with New Guinea or are closely related to New Guinea species, for example *Agrostis reinwardtii*, *Danthonia oreoboloides*, *Poa papuana*, and *Drapetes ericoides*.

Grasslands and Herb Fields

A common type of alpine grassland is dominated by robust tussocks of *Deschampsia klossii* that grow to 60 cm high. This grassland usually occurs on deeper soils on slopes and along the banks of streams. At high elevation, the grass is viviparous, with seeds sprouting on the parent plant. Other grasses include *Anthoxanthum redolens* and *Poa nivicola* and gaps in the tussocks have a rich mat of *Poa* spp., *Cerastium* sp., *Geranium monticola* and *Epilobium detznerianum*.

Short alpine grassland, with small tussocks of *Poa erectifolia* and *P. lamii*, dominates Mt. Albert Edward, but similarly structured grasslands with other dominants occur on other mountains (Fig. 8). Small tussock and tuft grasses that include *Deyeuxia brassii*, occur with scattered low shrubs of *Coprosma*, *Vaccinium*, and *Rhododendron* species.

Astelia alpina alpine herb field is widespread with *Astelia* cushions forming large stands on some mountains, such as the Star Mountains and Mt. Giluwe (Fig. 9). Small cushion plants, including *Centrolepis philippinensis*, *Potentilla brassii*, *Oreomyrrhis pumila*, and *Danthonia oreoboloides* and *Oreobolus pumilio* and occasional grasses are often important. Such cushions extend into waterlogged areas, forming a cushion bog. This bog type is notably more common in the Snow Mountains of Papua than in PNG.

Fig. 8 Short alpine grasslands at 3990 m dominated by *Poa* and *Danthonia* species, Mt. Wilhelm. Shrubs are *Coprosma* sp.

Fig. 9 *Astelia alpina* herb field and *Gleichenia vulcanica* fernland. The large tussocks are *Deschampsia klossii* on Mt. Giluwe, PNG.

Alpine moss lands. Structurally these communities, dominated by a carpet of mosses, resemble boreal moss communities. On waterlogged or inundated sites *Ranunculus* spp. are interspersed with the mosses (Fig. 10), but on stable screes a complex of mosses with small cushions of *Cerastium*, *Potentilla* or *Oreobolus* support small tuft grasses that grow in the moss.

On drier sites such as moraine and rock surfaces, mosses form a discontinuous carpet with scattered herbs such as *Epilobium* and *Plantago* and small grasses (Fig. 11). Small shrubs of *Styphelia suaveolens* may also be present, as noted by Mangen (1993) on Mt. Trikora.

Wade and McVean identified these moss lands as wet or dry tundra. However, alpine grasslands and open heaths occur at the same elevation on more mature soils. Hence these moss lands are probably time-limited and will eventually give way to alpine grasslands or grass-dominated bog. The mosses cover the ground and quickly reduce the pH on calcareous sites, providing an acid organic substrate (Hope, 1976).

Fig. 10 Alpine moss land with *Ranunculus* sp. in the Yellow Valley on Mt. Jaya at 4450 m altitude.

Fig. 11 These *Rhacomitrium* moss lands on Mt. Wilhelm summit at 4420 m are developing in an area that was probably covered by firn (granular snow) prior to 1860.

Wetlands

Sedges dominate several types of alpine fen with varying degrees of inundation. *Carpha alpina* fen is characteristic of less wet sites with robust small tussocks (Fig. 12). *Carex gaudichaudiana* dominates pond edge fen with *Isolepis crassiuscula* in semi-permanent shallow ponds. *Uncinia riparia* also forms a closed sedge land on Mt. Trikora (Mangen, 1993). Related fens extend through the alpine of Australia to the sub-Antarctic, possibly reflecting the role of migratory birds in spreading wetland plants.

Elements of these New Guinean alpine communities reach Mt. Kinabalu and indeed Mauna Loa in Hawaii has related *Styphelia*, *Anthoxanthum*, *Festuca*, and *Coprosma* species. Yushan has a Himalayan element including *Gentiana* spp. and *Rhododendron pseudochrysanthum*. These genera have radiated in the New Guinea mountains, presumably reflecting the newness of high mountain

Fig. 12 Fringing fen of *Carpha alpina* and *Astelia* around a tarn, Mt. Victoria, PNG.

environments in New Guinea. This also explains the high level of southern temperate taxa such as *Astelia* and *Poa* that have migrated to the region.

Fauna

In Taiwan, voles (*Microtus kikuchii*) are common in high elevation meadows and help to spread their main food grass, *Yushania nii-takayamensis* (Yeh et al., 2012). Elsewhere, rat species are major herbivores in alpine grasslands. Mt. Kinabalu hosts four mammal species in the summit area—the Summit Rat (*Rattus baluensis*), the Kinabalu Shrew (*Crocidura baluensis*), the short-tailed Gymnure (*Hylomys suillus*) and the mountain squirrel (*Callosciurus baluensis*) (Wong and Chan, 2015). The Blackbird (*Turdus poliocephalus*) is common there and also in the New Guinea alpine, where rats such as *Rattus niobe* and *R. giluwensis* live in alpine grasslands. The Glacier Rat (*R. richardsonii*) occurs up to the highest elevations in rocky terrain. Remains of the 3 kg Giant New Guinea Rat (*Mallomys istapantap*) have also been collected at 4430 m elevation on Mt. Jaya (Hope et al., 1976) even though it is thought to be largely folivorous (leaf-eating). Marsupials are present, though they are found only occasionally in the alpine zone. The bandicoot *Microperoryctes longicauda* is an insectivore closely resembling the shrews of Kinabalu. Wild dogs (*Canis lupus*) introduced to New Guinea about 3500 years ago, are quite common in the alpine zone and reflect the high density of rodents.

Birds such as the Blackbird, Glossy Swiftlets (*Collocalia esculenta*), the island thrush, (*Turdus poliocephalus*), the alpine robin (*Petroica archboldi*) and the New Guinea pipit (*Anthus gutturalis*) exploit a sparse insect population in the alpine. Alpine lakes are also visited by Salvadori's Teal (*Anas waiguensis*) and other water birds that feed on invertebrates and water plants. A feature of tropical high mountains is a rain-out of dead insects and even lowland bird species brought up by powerful updrafts, adding to the food resources of predators and scavengers in the summit zone (Schodde et al., 1975).

Human Usage

The tropical high mountains are cold, cloudy and wet, so do not provide an opportunity for agriculture. Prior to modern tourism, the alpine received infrequent visitors. In some cases, such as Kinabalu, the peaks were considered sacred and so were not visited. In western New Guinea there are tracks traversing the range and crossing the alpine zone (Fig. 13). Hunting takes place in the alpine and subalpine grasslands. A rock shelter in the alpine of Mt. Jaya at 4200 m has a basal age of 6200 cal years BP (Hope et al., 1976). It is likely that people have exploited the alpine throughout the Holocene as vegetation histories show the presence of fire from 12,000 years ago in some areas (Fairbairn et al., 2006). However, mountains such as Mt. Wilhelm and Mt. Giluwe experienced forest disruption quite recently with clearance due to fire over the last several centuries (Corlett, 1984; Hope unpublished). This may reflect increasing human populations at lower elevations who exerted pressure to exploit the mountains for mammals and birds. This use of the mountains for transit and hunting continues to the present though may be reducing in some areas.

Fig. 13 This grassland area of the snow mountains near Mt. Trikora has been burnt over the past 11,000 years.

This long history explains some of the mosaic of subalpine forest and grasslands, together with a fragmentation of the treeline in some mountain areas such as Mt. Albert Edward and Mt. Jaya. Many grassland and herb field species have expanded into lower elevation niches as the subalpine forests retreated and were replaced by grasslands.

Over the past 50 years tourism has expanded greatly, such that permits to ascend Yushan and Kinabalu have had to be limited. Thousands of visitors follow the most popular tracks. New Guinea is a far less popular tourist destination, although guided tours of Mount Wilhelm take place and other mountains such as Mt. Giluwe and Mt. Trikora are accessible from nearby towns. Mount Jaya attracts numerous climbing expeditions, as it is one of the seven world summits, the highest point in Oceania.

The summit of Mount Albert Edward has microwave facilities serviced by helicopter and similar facilities have been abandoned on Mt. Wilhelm and Mt. Giluwe. Mining on Mt. Jaya has removed several km² of alpine habitat due to the mining of gold and copper at Grasberg and the dumping of tailings up to 4200 m.

Abstract

The temperate zone mountains of North America contain alpine ecosystems whose distinctive plant and animal communities are adapted to the cold temperatures, winter snow cover, short growing seasons, and high winds found in the steep rocky terrain at high elevations. Although 3% of the land area is alpine, the alpine zone contains 4% of the world's flora and is therefore richer in biodiversity than expected. At the landscape scale (>100 m), wind and snow interact with landforms to form mesotopographic gradients along hillslopes. Snow redistributed by winds produces long-lasting snowdrifts on lee slopes, which increase water availability downslope, but also affect the timing and length of the growing season for plants. Along the gradient, cushion plant-dominated vegetation occurs on exposed ridgetops, followed by dry sedge meadows or dwarf-shrub heaths in less exposed positions below the ridge, moist meadows or heaths in early-melting midslope positions, late-melting snowbed vegetation, and wet meadows or bogs in valleys. Alpine plant adaptations to the harsh environmental conditions include short stature, cold tolerance, long lifespans, and vegetative reproduction. Animals cope with winter conditions by living in sheltered environments under snow and talus, hibernating, or migrating. The American pika, a potential sentinel species for climate change, is intolerant of warm temperatures and depends on winter snow cover. On Niwot Ridge in Colorado, minimum temperatures and precipitation are increasing, but declining precipitation has also been observed in the western US. Climate change and atmospheric deposition of nitrogen are likely to contribute to shifts in ecosystem properties and plant and animal species distributions, such as shrub encroachment into herbaceous communities.

Introduction

The mountains of North America are home to alpine ecosystems whose distinctive plant and animal communities are adapted to the cold temperatures, snow, and wind found in the steep rocky terrain at high elevations (Fig. 1). Alpine ecosystems occupy 3% of the land surface worldwide but contain 4% of the world's flora, and are therefore richer in than expected (Körner, 2003). In addition to this important contribution to global biodiversity, alpine ecosystems are valued for their aesthetic beauty and recreation opportunities. They also influence the quality and quantity of water and nutrients delivered to downslope areas, and may be sensitive indicators of global change factors such as climate and air pollution.

Plants in alpine ecosystems survive the harsh climate by hugging the ground (up to a few decimeters in height) and using the intense solar radiation during the growing season to produce vividly colored flowers in meadows and among low shrubs. Cushion plants (low compact herbaceous plants) and lichens may be found in the most severe conditions on exposed ridge tops and summits. Characteristic alpine plant growth forms are shown in Fig. 2. Year-round animal residents of the alpine zone of North America include pikas, marmots, ptarmigan, pipits, and rosy finches. Larger herbivores such as bighorn sheep, mountain goats, deer, elk, and moose may be seasonal visitors, along with many other birds and mammals (Armstrong et al., 2001).

Alpine ecosystems are found above treeline and below the permanent snow line, if one is present (Billings, 2000). Many mountains in North America have alpine vegetation growing from treeline all the way to the summit. Others have snow lines or nival zones above the alpine zone where plant growth is limited except in protected areas (Nagy and Grabherr, 2009).

Fig. 3 Krummholz trees and alpine vegetation at treeline on Niwot Ridge.

The transition from the taller crowns of forest trees to the diminutive stature of alpine vegetation is an obvious landscape feature of high mountains (**Fig. 3**). The tree “line” is actually part of a zone of transition or ecotone from closed canopy forests to open alpine ecosystems. At treeline, upright trees occur as patches that alternate with patches of herbaceous vegetation ([Bourgeron et al., 2015](#)). Alpine vegetation may also occur below treeline where disturbances such as avalanches have removed trees. In addition, dwarf trees (krummholz) may be found in protected locations above treeline. The ecotone is porous in nature because the factors that define the lower limits of alpine species are not necessarily those that limit the upward distribution of trees. Temperature, precipitation, and wind are all factors that influence the location of treeline and therefore the lower limit of the alpine zone. The elevation at which the average temperature during the growing season is 6 °C or lower roughly corresponds to this lower limit ([Körner and Paulsen, 2004](#)).

Alpine ecosystems are often referred to as alpine “tundra”, which implies a similarity with arctic tundra ([Billings, 2000](#)). Although both types have similar physiognomy, and alpine areas generally share species in common with the arctic zone, important differences exist in environmental conditions. Both ecosystem types have low temperatures during the growing season. However, alpine environments have greater solar radiation intensity, wind, snow cover, and topographic heterogeneity, but shorter daylength, and less permafrost compared to arctic systems ([Körner, 2003](#)).

Temperate Zone Mountains

The temperate zone limits in North America, for the purposes of this article, are those described by [Nagy and Grabherr \(2009\)](#). Their categorization was based on a combination of existing climate life zone classifications that use temperature and precipitation together with broad vegetation classes to delineate zones. The temperate zone is located between the more northerly boreal zone of Canada and Alaska and the subtropical zone of the southeastern and southwestern United States.

On the east coast of North America, the highest peaks in the northern Appalachian Mountains have limited alpine zones, such as the Adirondack Mountains in New York, the Presidential Range in New Hampshire, and Mt. Katahdin in Maine. Temperate zone mountains with alpine ecosystems include the two great western Cordilleras, the Coastal Cordillera and the Rocky Mountains (**Fig. 4**). Alpine environments in the Coastal Cordillera are found in the Coast Mountains of British Columbia and the Cascade Mountains in the Pacific Northwest (**Fig. 4A**). Alpine ecosystems in the Rockies occur in southern British Columbia and Alberta and in the western United States from Idaho and Montana to New Mexico (**Fig. 4B–D**). The Great Basin contains several isolated mountain ranges with alpine ecosystems.

The elevation of treeline (the lower limit of the alpine zone) varies among North American temperate zone mountain ranges, depending on overall height and prevailing climate conditions. Treeline in the northern Appalachian Mountains ranges from 1300 to 1600 m ([Carlson et al., 2011](#)). In the Cascade Mountains treeline occurs at about 2000 m ([Nagy and Grabherr, 2009](#)), and in the Rocky Mountains, treeline decreases from south to north. For example, on Wheeler Peak, New Mexico, it occurs at about 3700 m ([Baker, 1983](#)), whereas on Niwot Ridge in the Colorado Front Range, it is located at about 3500 m, and in Glacier National Park it ranges from about 1800 to 2100 m.

The tectonic age of temperate mountain ranges decreases from east to west. The relatively old Appalachian Mountains arose in the Cambrian to the Pennsylvanian, the Rockies in the upper Cretaceous to Oligocene, and the Coastal Cordillera in the Pliocene to

Fig. 4 Alpine areas in the temperate zone of North America, as defined by the GAP/LANDFIRE National Terrestrial Ecosystems project for the continental United States (US Geological Survey Gap Analysis Project 20,160,513, 2011, <https://doi.org/10.5066/F7ZS2TM0>) and the Canadian National Vegetation Classification. United States national, state, and local parks; other protected areas; and National Forests. Parks, ecological reserves, and protected areas in British Columbia and Alberta are parks and protected areas managed for important conservation values. Northern Appalachian and Great Basin alpine zones not shown due to small areal extents.

Pleistocene (Billings, 2000). Pleistocene glaciation affected mountains throughout the temperate zone. Continental ice sheets covered mountains in the northeastern and northwestern mountain ranges, whereas local ice caps and glaciers shaped interior western ranges south of the ice sheets. Extensive reshuffling of biotic distributions occurred during this period (Elias, 2001).

Environmental Factors

Climate

Cold temperatures, winter snow cover, short growing seasons, and high winds characterize alpine environments in temperate North America. Temperature decreases with increasing elevation, but the extent differs with latitude, atmospheric circulation pattern, and geographic position on the North American continent and may also be altered locally by wind, slope, and aspect (Nagy and Grabherr, 2009). Aboveground air temperatures do not necessarily reflect temperatures at the soil surface or in the canopies of plants, which may be much higher due to absorption of solar radiation and the high aerodynamic resistance of short-statured alpine plants (Billings, 2000). These differences depend on weather, time of year, time of day, and individual plant species characteristics (Körner, 2003). In addition, diurnal fluctuations in temperature may be quite large, exposing plants and animals to the stresses of temperature extremes over short time periods (Nagy and Grabherr, 2009).

An important factor that distinguishes the temperate zone of North America from other North American life zones is continentality, an increase in the range of temperatures in interior versus coastal areas (Nagy and Grabherr, 2009). Mountain ranges in the northeastern and northwestern temperate zone experience a greater degree of maritime influence on climate, which moderates temperature extremes compared to those occurring in the continental interior, that is the Rocky Mountain and Great Basin ranges. In the North Cascades, climate regimes shift from maritime to continental going from west to east. As a consequence of this shift, western North Cascade plant community types are more closely related to those in other west coast ranges, but eastern types have a greater resemblance to Rocky Mountain communities (Douglas and Bliss, 1977).

The amount of solar radiation received at a particular location in the alpine zone depends on elevation, slope, aspect, latitude, and position of the sun, creating microtopographic insolation gradients (Nagy and Grabherr, 2009). Incoming solar radiation increases with increasing elevation, especially in the UV range (Billings, 2000). However, cloudiness may also increase with elevation, attenuating the amount of solar radiation actually available to plants for photosynthesis (Körner, 2003). Cloud cover in the form of wet fog is a particularly important environmental feature of the alpine zone of the northern Appalachian Mountains on north and west-facing slopes, and is a contributing factor to the presence of a large number of Arctic plant species in the alpine ecosystem (Bliss, 1963).

Temperate zone mountain ranges are generally characterized by an abundance of winter snow (Nagy and Grabherr, 2009). Precipitation regimes vary both among and within mountain ranges due to geographic position, degree of continentality, and prevailing atmospheric circulation patterns. Although temperature regimes in the alpine zones of Mount Washington, New Hampshire, and Niwot Ridge, Colorado are similar (cool, short growing seasons), the north Appalachian Mountains experience a fairly even distribution of precipitation throughout the year, making summer drought unlikely (Billings, 2000). In contrast, 75% of annual precipitation occurs as snow in the southern Rockies (Greenland and Losleben, 2001), resulting in drier summers where precipitation occurs in the form of convective thunderstorms.

Geomorphology and Soils

Physical disturbances to plant and animal habitats range in size and intensity in alpine ecosystems as a result of the high topographic relief. Mass movement events can occur over short time scales, for example, snow or rock avalanches, or can take a longer time to manifest, for example, development of scree and talus slopes or glaciers (Nagy and Grabherr, 2009). Some small mammal species inhabit scree and talus slope habitats, such as pikas (*Ochotona princeps*), marmots (*Marmota flaviventris*), and deer mice (*Peromyscus maniculatus*) (Armstrong et al., 2001). Rocky slopes are sparsely occupied by plants, but provide habitat for some species, for example, *Saxifraga* and *Draba* species (Walker et al., 2001).

Alpine soils are cold and, depending on topographic position, range from dry to wet (Billings, 2000). The harsh climate limits the amount of chemical weathering, but intensive freeze-thaw cycles may break rock down (Seastedt, 2001). In soils containing moisture, rock and gravel may be brought to the surface, producing patterned ground features such as stone nets, stripes, and circles, as well as solifluction lobes. At a fine scale, frost churning produces needle ice, frost boils, and frost creep, which can be disruptive to plants. However, plant communities with a complete ground cover can provide insulation against frost disturbance (Körner, 2004).

Soil development is a function of position in the landscape, with the least developed soils occurring in both windblown and snow accumulation areas because insufficient biotic-related weathering takes place (Seastedt et al., 2004). Although overall nutrient levels tend to be low in alpine soils, they vary spatially. Nitrogen increases from dry to moist to wet meadows (Suding et al., 2015).

Mesotopographic and Microtopographic Gradients

In the alpine zone, topography, wind, and snow combine to determine the conditions under which plants and animals live. At the landscape scale (> 100 m), wind and snow interact with landforms to form mesotopographic gradients along hillslopes (Fig. 5). The mesotopographic model developed by Billings (2000) has been used to explain plant and animal distributions in a number

Fig. 5 Mesotopographic-scale snowdrifts in the Saddle site on Niwot Ridge. Foreground, windward slope; background, lee slope.

of temperate zone alpine sites (see below). Ridgetops, midslopes, and bottom slopes differ in the amount of snow cover and its duration. Snow falling on mountains may be blown from windward-facing slopes by strong winds and redeposited on leeward-facing slopes, leading to the accumulation of long-lasting snowdrifts on these slopes (Fig. 5). Snow drifts increase water availability downslope and provide protection from wind, cold temperatures, and frost effects, but also constrain the timing and length of the growing season for plants. On Niwot Ridge, the growing season on a windswept ridgetop with little snow accumulation was 109 days, but was only 52 days for a wet meadow area with a late-lying snowpack (May and Webber, 1982). Soil moisture varies across the mesotopographic gradient as a function of snowpack and meltwater supply, with the lowest soil moisture values at the top of ridges and the highest values at the foot of slopes where meltwater accumulates (Walker et al., 2001). The landscape continuum model developed by Seastedt et al. (2004) couples the mesotopographic approach with an emphasis on transport processes as organizing agents of ecosystems. Transport of materials occurs by means of wind, water, avalanches, and landslides. For example, alpine areas at the bottom of slopes receive water and nutrient inputs from upslope areas.

Alpine ecosystems are affected by microtopographic differences at spatial scales less than 10 m (Suding et al., 2015). Mosaics of microhabitats occur as a result of features like small depressions, rocks, and plants themselves. Microdrifts of snow accumulate in the lee of rocks and plants (Fig. 6). Small-scale heterogeneity in slope and aspect generates variation in solar radiation; other microhabitat factors include wind protection, soil temperature, and soil nutrients. These factors are the same as those influencing biotic distributions at the landscape scale (Suding et al., 2015). Micro-environmental mosaics constrain the biota and are in turn altered by biotic processes. The combination of meso- and microtopographic gradients in alpine landscapes produces transitions between plant, animal, and microbial communities (beta diversity) over short horizontal distances within the larger landscape-level gradients.

Biodiversity

Vegetation

The applicability of the mesotopographic concept for understanding alpine vegetation patterns has been demonstrated for several North American temperate zone locations. A common topography/snow/meltwater gradient consists of cushion plant-dominated vegetation on exposed ridgetops, followed by dry sedge meadows or dwarf-shrub heaths in less exposed positions below the ridge, moist meadows or heaths in early-melting midslope positions, late-melting snowbed vegetation, and wet meadows or bogs in valleys (Billings, 2000).

Alpine vegetation patterns at Niwot Ridge in the southern Rocky Mountains have been explained as resulting from a mesotopographic gradient in snow (Fig. 7) (Walker et al., 2001). Fellfield communities occur in the most windswept, exposed positions where plant cover is sparse and cushion plant life forms dominate. Characteristic fellfield species are cushion plants such as *Silene acaulis* (moss campion) and *Minuartia obtusiloba* (twinflower sandwort), the mat-forming plant *Trifolium dasyphyllum* (alpine clover), and *Carex rupestris* (curly sedge). This rocky, dry habitat is blown free of snow in the winter. Just below ridgetops on windward slopes, dry meadow communities have little winter snow cover and are dominated by a sedge species, *Kobresia myosuroides* (Bellardi bog sedge), which forms dense turfs. *Kobresia* is unable to survive the harsh winter conditions in fellfields. It also appears to require

Fig. 6 Microtopographic-scale snowdrifts. (Top) Niwot Ridge and (bottom) Beartooth Plateau, Montana.

a long snow-free period in spring and fall and does not survive in habitats where snow cover routinely develops early. The club moss *Selaginella densa* (Rocky Mountain spikemoss) is also abundant in dry meadows. Another sedge species, *Carex elynoides* (blackroot sedge), occupies a smaller areal extent than *Kobresia* on relatively dry south slopes. This species is more abundant in other Rocky Mountain locations that lack *Kobresia*. Moist meadow communities occur on lower slopes where snow cover is moderate but melts relatively early in the growing season and soil moisture is abundant. The dominant species in this community type are a grass species, *Deschampsia cespitosa* (hairgrass), and a forb (herbaceous flowering plant), *Geum rossii* (Ross' avens), which is also present in most other communities. Late-lying snowbanks on lee slopes are the locations of snowbed communities, characterized by *Sibbaldia procumbens* (a forb, creeping sibbaldia), and *Carex pyrenaica* (Pyrenean sedge). These habitats have a very short growing season, and soil moisture disappears rapidly following snowmelt, producing sparse vegetation. Wet meadow communities occur downslope from snowbeds, where meltwater provides abundant soil moisture during most of the growing season. *Carex scopulorum* (mountain sedge), and *Caltha leptosepala* (a forb, white marsh marigold) are the dominant species. The shrub community type has a fairly continuous cover of *Salix* (willow) species, and is found in protected areas near the bottom of the slope.

Baker (1983) studied alpine community types in the Sangre de Cristo Mountains of New Mexico along a mesotopographic gradient similar to Niwot's. The species composition of most communities resembled those occurring on Niwot, but also included some community types that were not equivalent, such as a *Festuca thurberi*-dominated community on very steep southeast-facing slopes.

Billings and his associates conducted research at several western United States temperate alpine sites and related vegetation mosaic patterns to mesotopographic snow gradients (Billings, 2000).

Fig. 7 Hillslope positions along a mesotopographic gradient and associated plant community types in the Saddle site on Niwot Ridge, elevation ~3520 m. Fellfield occurs on windswept ridgetops, dry meadow on windward slopes with low winter snow cover, wet meadow at the bottom of slopes in areas of meltwater accumulation, moist meadow on lower slopes with moderate snow cover, and snowbed on lee slopes with late-melting deep snow.

Plant communities occurred along a steep snow cover/soil moisture/wind gradient in the Medicine Bow Mountains of Wyoming, about 100 km north of Niwot Ridge. The Medicine Bow communities were similar to those found at Niwot, with the notable exception that Niwot's dominant dry meadow species, *Kobresia myosuroides*, was absent. At a windward location below the ridgetop, the rocky slope was sparsely vegetated with an open fellfield community rather than a sedge-dominated turf.

On the broad expanses of alpine vegetation on the Beartooth Plateau of Wyoming and Montana, [Johnson and Billings \(1962\)](#) found that plant communities were structured similarly to those of Niwot along a snow mesotopographic gradient. As in the Medicine Bow Range, the characteristic Niwot dry meadow community did not occur. However, a species with similar habitat requirements, *Carex elynoides* (blackroot sedge), was present in dry environments. A possible contributing factor to the low abundance of *Kobresia myosuroides* on the Plateau was a smut found on 15% of plants that were examined. As at Niwot, microtopographic differences in snow accumulation produced a mosaic of microhabitats within major vegetation types. Soil frost activity was an important driver of geomorphic processes on the Beartooth Plateau. Frost-churned peat hummocks ([Billings, 2000](#)), disturbed *Deschampsia* meadows, producing fine-scale vegetation heterogeneity. Taller hummocks, which melted out earlier than lower ones, were dominated by *Deschampsia cespitosa* and *Carex scopulorum*. *Juncus drummondii* completely covered some lower hummocks, but only occurred on the sides of higher ones. The intervening troughs contained *Caltha leptosepala*, *Juncus* (rush), and *Salix* species. On the relatively gentle slopes that occurred on the Plateau, plant community boundaries were not distinct, grading into a continuum.

In the North Cascades, the mesotopographic gradient followed the general pattern outlined by [Billings \(2000\)](#). Mosaics of plant communities were more common in the western North Cascades as a result of more complex topography and greater snowfall, whereas community transitions were more gradual on the gentler eastern slopes, which have a drier environment ([Douglas and Bliss, 1977](#)). The dominant species in the vegetation types differed in eastern versus western alpine ecosystems. The western North Cascades showed greater affinity to other west coast ranges but the eastern North Cascades were more closely related to the Rocky Mountains and southern Yukon and Alaska.

[Bliss \(1963\)](#) described vegetation-environmental relationships in the Presidential Range of the Northern Appalachians, in which plant community types were associated with two rather than one mesotopographic gradient. A snow accumulation/wind gradient ranged from a *Diapensia*-dominated community on ridgetops with little snow cover, to well-drained heath-rush, early-melting heath, and late-melting snowbed in deep depressions. Bog and streamside communities occurred at protected lower elevation sites. The second gradient in atmospheric moisture ranged from fog-adapted sedge meadow on high elevation north and west facing slopes, to sedge-heath, sedge-rush-heath, and heath-rush, culminating with heath, the least foggy community in the gradient.

The dominant sedge in the alpine zone was *Carex bigelowii* (Bigelow's sedge). *Juncus trifidus* (highland rush), *Sibbaldiopsis tridentata* (shrubby fivefingers, an evergreen forb), and *Minuartia groenlandica* (Greenland stitchwort, a cushion) were also abundant. As in the Cascades and other northwest locations, ericaceous dwarf shrubs, such as *Diapensia lapponica* (pincushion plant) and *Vaccinium vitis-idaea* (lingonberry), were important components of the flora in contrast to the southern Rocky Mountains where they are not represented, probably due to a drier environment.

Plant Species

Plant species richness decreases with increasing elevation on mountains, but because alpine plants are small and microtopographic heterogeneity provides a diverse mosaic of habitats, a small patch of ground may contain many alpine species. In fact, species richness is higher per unit area than in almost any other herbaceous vegetation type (Bowman, 2000). Abrupt changes in species composition may also occur across relatively short distances (< 10 m). Alpine plants are generally long-lived perennials that tolerate low temperatures and nutrient availability, have low growth rates and short stature, and reproduce primarily by vegetative means, although seedling recruitment occurs on disturbances (Walker et al., 2001). They can be categorized by type of growth form. Fig. 2 shows four of the most important growth forms in the temperate alpine zone of North America.

Alpine plants have adapted to the short growing season by preforming leaf and flower buds one or more years in advance, which allows plants to leaf out as soon as conditions permit in the spring. In some species, this growth occurs under snow before meltout. They invest less biomass in stems and more biomass in roots than lower elevation plants, resulting in a high root to shoot ratio. These adaptations are conservative strategies that enable survival in a harsh environment (Gasarch and Seastedt, 2015). However, they also constrain potential responses to changing conditions (Bowman, 2000).

Vertebrate Species

Few vertebrates are restricted solely to alpine habitats, but a number of species are visitors over varying periods of time. In a survey of vertebrates in the alpine zone of the Cascades and northern Rocky Mountains, species richness was lowest in alpine ecosystems (46 species), but the set of species occurring in the alpine zone had low overlap with those in other ecosystems, making a significant contribution to vertebrate diversity (Raphael et al., 2002). Vertebrates occurring in alpine ecosystems were also found to occupy greater elevation ranges and more plant community types than those in other ecosystems.

The white-tailed ptarmigan (*Lagopus leucurus*) is a year-round resident in the Colorado alpine zone, but some ptarmigan winter in the subalpine zone. Bird species other than ptarmigan that breed in the alpine zone of Colorado are the horned lark (*Eremophila alpestris*), the American pipit (*Anthus rubescens*), the white-crowned sparrow (*Zonotrichia leucophrys*), and the brown-capped rosy finch (*Leucosticte arctoa*) (Armstrong et al., 2001). In the Columbia River Basin, four bird species are listed as occurring solely in alpine habitat. They consist of the white-tailed ptarmigan, American pipit, black rosy finch (*Leucosticte arctoa*), and gray-crowned rosy finch (*Leucosticte tephrocotis*) (Raphael et al., 2002). A number of other bird species occupy alpine habitats seasonally or migrate through these areas. American robins (*Turdus migratorius*) and mountain bluebirds (*Sialia currucoides*) are common summer visitors to the alpine zone.

Small mammal species that are commonly found year-round in temperate North American alpine ecosystems include pikas, northern pocket gophers (*Thomomys talpoides*), marmots, and snowshoe hares (*Lepus americanus*), as well as species of weasels, squirrels, chipmunks, mice, voles, and shrews. Marmots survive the winter by hibernating, accumulating fat reserves during the growing season. Pikas and other small mammals such as pocket gophers and voles cache food for later consumption, but only pikas store enormous "haypiles" (~30 kg for a < 200 g animal).

American pikas are charismatic small mammals inhabiting the alpine zone where they occupy talus and boulder fields but also occur in lower elevation rocky habitats (Erb et al., 2011). They have widely been considered a sentinel species for the effects of climate change because of their low tolerance for warm temperatures and dependence on winter snow cover for survival in alpine habitats. Pikas are non-hibernators, collecting and caching food for the winter in haypiles that largely consist of forbs, especially *Geum rossii* in Colorado, whereas their summer diet consists mainly of graminoids. They may be affected by reductions in forb biomass and lack of snow cover in the winter, for example during drought years. Secondary compounds in *Geum* may act as preservatives of forage stored in haypiles (Dearing, 2001).

The northern pocket gopher is a small burrowing mammal with fur-lined cheek pouches that has been described as a "keystone species" because of its substantial effects on biogeochemical and geomorphic processes (Seastedt, 2001). Pocket gophers bring excavated soil to the surface to produce soil heaps or "gopher mounds", which bury existing plants (Sherrod et al., 2005). On Niwot Ridge and elsewhere, pocket gopher activity is highest in moist meadow communities, but also occurs in other communities such as those dominated by *Carex elynoides*. Higher species richness on mounds may contribute to maintaining biodiversity in the communities gophers inhabit. Abandoned gopher tunnel systems may degenerate into areas of miniature terracettes, a widespread kind of small terrace with riser and tread features (Nagy and Grabherr, 2009).

Large herbivores that are widespread in the temperate alpine zone include bighorn sheep (*Ovis canadensis*), elk (*Cervus canadensis*), and moose (*Alces alces*). Large carnivores, such as wolves (*Canis lupus*) and grizzly bears (*Ursus arctos*) have been extirpated from many locations in the continental United States, and with the exception of some national parks, these are now restricted to northern regions of the temperate zone.

All alpine ecosystems are grazed, whether by the native fauna or introduced animal species (Körner, 2003). Alpine plant species produce secondary compounds as a defense against herbivory, such as tannins, which had the highest values in *Geum rossii* on Niwot Ridge (Dearing, 2001). Some aspects of plant herbivory appear to promote the expansion of graminoids, such as a preference for forbs by some herbivores, and deposition of nutrients in urine and feces, both of which favor graminoids. However, other species such as elk prefer graminoids to forbs; these opposing preferences may balance each other.

Anthropogenic Impacts

Following European settlement, grazing and mining in temperate zone mountains caused large-scale disturbances whose effects on alpine ecosystems have been long lasting. Many thousands of domestic sheep were pastured on alpine vegetation during the late 1800s and early 1900s throughout the Rocky Mountains and Great Basin (Billings, 2000). During the past 50 or more years, live-stock grazing on public lands generally has been either closely regulated or phased out, but the impacts of previous grazing may continue to affect the abundance and species composition of the vegetation in alpine ecosystems (Nagy and Grabherr, 2009). On Niwot Ridge, willow shrubs (*Salix* species) were found to have expanded more than 400% over 62 years, primarily by clonal growth (Formica et al., 2014). In 1949, when the US Forest Service halted sheep grazing on the Ridge, rangers recorded the alpine vegetation as degraded with few willows. Experiments conducted in the alpine zone have shown that increased nitrogen and temperatures facilitate willow growth; both are anthropogenic impact factors (see below) that may lead to increased woody encroachment in alpine ecosystems.

Alpine ecosystems can take decades to recover from damage incurred by recreational use. The results of pedestrian trampling on alpine vegetation were examined over a 42-year period in Rocky Mountain National Park, Colorado (Willard et al., 2007). Trampling had occurred in an alpine dry meadow site for 26 years before sampling was initiated. The trajectory of recovery illustrates the difficulty of reestablishing vegetative cover once it has been degraded, especially for dry meadow dominated by *Kobresia myosuroides*, which can only recolonize by vegetative growth from the remaining individuals. Although plants colonized and spread during some periods of time, two decades after the start of sampling recovery was severely set back due to unchecked soil erosion and several years of heavy snow accumulation. It is now thought that at least a century will be required for this vegetation to fully recover.

In recent years, ski area development has dramatically increased in the United States and elsewhere. The expansion and maintenance of ski resorts and ski runs impacts high elevation habitats, which are vulnerable to erosion and recover slowly after disturbances to the vegetation (Martin, 2015). Climate warming is likely to lead to upward shifts in the elevations that have snow suitable for skiing, increasing the use of alpine environments.

Global Change Effects

Nitrogen Deposition

Human activities such as burning fossil fuels and the use of inorganic nitrogen as a fertilizer generate emissions of atmospheric nitrogen that have important impacts on the biosphere.

Nitrogen deposition from anthropogenic sources doubled in the United States between 1961 and 1997 (Bobbink et al., 2010). Atmospheric nitrogen deposited in the alpine zone is an important factor in both the northeast and western regions of the temperate zone. On Niwot Ridge, the deposition rate has been measured at 6 kg N ha^{-1} . This rate is higher than the critical load estimated to affect sensitive plant species (4 kg N ha^{-1}) but lower than the critical load that indicates alpine community response (10 kg N ha^{-1}) (Bowman et al., 2015).

An increase in the supply of nitrogen affects plant production as well as plant and microbial species composition. In the alpine zone of Colorado, the community that is most susceptible to the influence of increased nitrogen is moist meadow, because it is dominated by both a nitrogen-limited species, *Deschampsia cespitosa*, and a nitrogen-insensitive species, *Geum rossii*. The addition of nitrogen to the system results in competitive displacement of *Geum* by *Deschampsia*. A positive feedback to nitrogen inputs can develop that increases nitrogen export from the community, due to net nitrogen mineralization rates that are up to 10 times higher in soils occupied by *Deschampsia* than *Geum*. This disparity produces microscale heterogeneity in nutrient distributions. However, increased nitrogen deposition could overwhelm this heterogeneity, resulting in changes to plant communities such as a decline in *Kobresia* abundance in dry meadows and an increase in *Deschampsia* in moist and wet meadows (Bowman et al., 2015).

Climate Change

Climate change is affecting alpine communities throughout the world; this may arguably be the greatest threat to their biodiversity (Erb et al., 2011). Warming temperatures would be expected to potentially have profound effects in a cold-limited environment. In the alpine zone at Niwot Ridge, minimum temperatures have been increasing since the 1950s (McGuire et al., 2012). The potential consequences of precipitation changes are great for alpine ecosystems due to the importance of snow as a primary driver of ecosystem response. In addition, meltwater from mountain snowpacks in the western United States is critical for maintaining downstream water supplies for human use. At Niwot Ridge, precipitation substantially increased from the 1950s to 2010 in the alpine zone, occurring primarily in winter and early spring (Kittel et al., 2015). In contrast to the results for Niwot Ridge, significant

declining trends in snowpack were found at many monitoring sites in the western United States. Declines extended across all months, states, and climates, but were largest in spring, in the Pacific states, and in locations with a mild winter climate (Mote et al., 2018).

The physiological adaptations of alpine species to cold environments, as well as their geographic constraints, may leave them especially vulnerable to climate warming (Erb et al., 2011). The American pika has disappeared from locations that were previously inhabited. This loss has been attributed to climate warming. However, a recent comprehensive survey of pika habitat in the Great Basin found pikas living in habitats they were not previously known to occupy, including warmer, drier sites as well as wetter, colder sites (Millar et al., 2018), leading to the conclusion that they can tolerate a wider range of conditions than previously thought, and suggesting that other factors in addition to climate may control pika distributions.

Conservation

Many alpine areas in temperate North America have at least some degree of protection from development. Fig. 3 shows overlap of the temperate North American alpine zone with extents of parks, other protected areas and National Forests, as an indication of the extent of protected areas, since National Forest lands include wilderness areas, but also lands that are managed for multiple use where conservation may not be assured. Due to the iconic status of scenic mountain peaks, alpine ecosystems are often well represented in parks and wilderness areas compared with lowland ecosystems. However, the popularity of many areas leads to heavy recreational use, as described above, especially in mountains easily accessible from major metropolitan areas.

Malanson et al. (2009) proposed actions that could be taken to mitigate the effects of climate change on alpine vegetation with the goal of preserving biodiversity. Direct actions include reducing non-climate stressors such as controlling the spread of invasive species, since climate itself cannot be controlled, and realigning the boundaries of reserves to encompass areas where species might be expected to be able to persist under climate change.

Conclusions

The plant, animal, and microbial species in alpine ecosystems of the North American temperate zone that are present today are those that have passed through a strong filtering process imposed by the severe environment, including cold temperatures, wind, snow cover, and short growing seasons. Biodiversity is enhanced by spatial heterogeneity in the form of repeatable landscape elements that provide a variety of habitats at meso- and microtopographic scales. However, anthropogenic impacts to alpine environments are testing the resilience of these valued ecosystems. Loss of biodiversity is a potential outcome as ecosystem properties and sensitive species distributions shift in response to climate change, nitrogen deposition, and human use.

Abstract

The temperate Andes are climatically, topographically and floristically very diverse. The dry temperate Andes (30°–37°S) reach elevations > 5000 m and are arid or semiarid. The wet temperate Andes (37°–55°S) rarely reach 3000 m elevation and receive higher annual precipitation. Although alpine vegetation of the temperate Andes is generally found in areas with growing season temperatures below 9°C, the effect of latitude and the north-to-south and east-to-west precipitation gradients result in differences in species composition and treeline elevation. Alpine areas of the dry temperate Andes are generally found above 3000 m and are bounded by xeric woods, matorral, and steppe. In contrast, the alpine areas of the wet temperate Andes are surrounded by *Nothofagus* forest or *krummholz*, and in this region, the treeline descends with latitude from ca. 2000 m in the north to ca. 500 m in the south. At the local scale, abiotic factors such as precipitation, elevation, aspect, and related temperature differences are the major determinants of floristic variation and species richness in alpine regions of the temperate Andes. On a larger scale, at different latitudes with different precipitation, species richness increases in the southernmost wettest sites. In all sites, the number of species is higher at intermediate elevations, with decreasing species richness toward the extremes. The higher levels of plant diversity at middle elevations are related principally to the effects of positive plant-plant interactions. Therefore, patterns of diversity in the high temperate Andes can be attributed to abiotic (mostly climatic) variables, but also to biotic interactions, for instance, owed to nursing cushion plants. Biotic interactions can play an important role as evolutionary drivers of alpine plant diversity, challenging the assumption that only large-scale abiotic phenomena such as climate, geomorphology and historical processes regulate alpine plant diversity.

Introduction

Mountains provide opportunities for adaptive evolution by increasing spatial heterogeneity of the landscape and thus generating a wide variety of environments. They also produce complex climatic gradients, promoting speciation through phenotypic divergence. In addition, they affect the migration of organisms and the distribution of species since mountain ranges can act as both biological corridors and ecological barriers (Antonelli et al., 2018; Luebert and Weigend, 2014). As a result, mountains host a large proportion of the biological diversity on earth (Barthlott et al., 2007; Antonelli et al., 2018).

The Andes are the longest mountain chain in the world. From approximately 11°N to 55°S, they traverse > 7000 km, crossing the Equator, the tropic of Capricorn, and reaching the southernmost tip of South America. Their great north-south extension coincides with remarkable variations in climate, from wet to hyperarid and from tropical to temperate. However, the higher elevations of many of its cordilleras, with numerous mountains reaching > 5000 m, result in the presence of a long strip of more-or-less continuous, open, cold terrain along the west of South America, above the lower forests or shrublands. This high Andean terrain has served as both a bridge and a barrier in the evolutionary history of many plant lineages from the New World, and currently contains a unique, rich and diverse flora (Luebert and Weigend, 2014).

The beauty and distinctive characteristics of the alpine flora of the Andes has attracted botanists since the early 19th century. The botanical expedition of Humboldt and Bonpland to Central and South America, that included the ascent to Volcán Chimborazo in Ecuador, resulted in the first descriptions of high-elevation plant communities of the tropical Andes in their *Tableau Physique des Andes et Pays Voisines* (Humboldt and Bonpland, 1805). Some decades later, Weddell (1857) published *Chloris andina: essai d'une flore de la région alpine des Cordillères de l'Amérique du Sud*, in two volumes of rigorous descriptions and beautiful illustrations of plants of Andean high elevations, thus initiating the study of alpine plant diversity of the Andes, both tropical and temperate.

In recent times, a renewed interest in the origin, characteristics and determinants of floral diversity of the Andes has produced several studies on alpine plant diversity of the mountains of South America. Although the tropical Andes are well known for high levels of diversity and endemism of their mountain floras, the alpine flora of the temperate Andes has been less well-studied. Even though the levels of richness and endemism of the temperate alpine Andes are probably less than those of the tropical Andes (e.g., Barthlott et al., 2007), the unique traits and probable antiquity of the flora of the former makes them especially important (Luebert and Weigend, 2014). Here we describe the characteristics of the high elevation flora of the temperate Andes and the main patterns and determinants of alpine plant diversity in this region.

Physical Setting

The Andes are divided into Northern, Central and Southern sectors that are biogeographically differentiated (Luebert and Weigend, 2014). The alpine areas of these sectors mostly comprise the high elevation Páramo (in Colombia, Ecuador and northern Peru), the elevated Puna altiplano (in southern Peru, northern Chile, southwestern Bolivia and northwestern Argentina), and the extra-tropical high-Andean portion corresponding to temperate latitudes (in central and southern Chile and Argentina), respectively (Cabrera and Willink, 1980; Olson et al., 2001). In this article, the temperate Andes are defined as the portion extending south of the Puna to the tip of South America, i.e., approximately from 30°S to 55°S. This extratropical southern portion of the Andes is also delimited to the north by a climatic and biogeographic barrier, the hyperarid Atacama Desert, which occupies an area from 18°S to 30°S in western South America (Arroyo et al., 1988; Squeo et al., 1994; Luebert and Weigend, 2014).

This southern area of the Andes is climatically, topographically and floristically very diverse (Fig. 1). Because of the climate, the temperate Andes can be divided into a northern, drier area from 30°S to approx. 37°S, in latitudes that mostly have a semiarid, temperate Mediterranean climate (the dry temperate Andes sensu Lliboutry, 1998), and a southern, more humid region from approx. 37°S to 55°S, in latitudes of mostly humid temperate oceanic climate (the wet temperate Andes sensu Lliboutry, 1998). These two areas also have different topography (Fig. 1A). The dry temperate Andes (DTA) are higher and less dissected by glacial features. They include the highest mountains of South America, such as Mount Aconcagua (6960 m) and Mount Tupungato (6800 m). The wet temperate Andes (WTA) are lower and are more dissected by glacially-carved landscapes at these higher latitudes. From the Great Patagonian Glaciation (GPG, ca. 1 Ma BP) to the last glacial maximum (LGM, ca. 25 ka BP), the WTA were repeatedly covered by continuous ice sheets from 37°S to 56°S (Rabassa et al., 2011). Currently, they are traversed by many lakes of glacial origin, and contain three important ice fields (Patagonian North, Patagonian South, and Cordillera Darwin; Lliboutry, 1998). Their mountains generally do not surpass 2500 m, with only a few peaks attaining ca. 4000 m, such as Mount Valentín (3910 m), Volcán

Fig. 1 Alpine areas of the temperate Andes. Map of southern South America indicating the regions (A) that exceed 2000 m asl, (B) that present a mean temperature during the growing season of $< 9.5^{\circ}\text{C}$. The dashed line separates the DTA (dry temperate Andes) in the north from the WTA (wet temperate Andes) in the south.

Lanín (3776 m) and Mount San Lorenzo (3706 m). Even though the mountains of the WTA are generally lower in altitude than those of the DTA, their higher latitude fosters open, treeless alpine environments on mountaintops.

The DTA, found from San Juan to northern Neuquén provinces of Argentina and from the regions of Coquimbo to Maule in Chile, are formed by several parallel ranges. From west to east, these include the Cordillera Principal, the Cordillera Frontal, and the Precordillera (Taylor, 1991). The WTA, from northern Neuquén in Argentina and bordering areas of Chile to Tierra del Fuego, consist mostly of the Patagonian Andes (Taylor, 1991). Some mountains higher than 2000 m are also found on the Patagonian sierras and mesetas to the east (Fig. 1A), but these and other elevated ranges of temperate southern South America, such as the Cordillera de la Costa in western Chile and the Sierras Pampeanas in central Argentina, are not included in this chapter. In general, these highlands do not attain >2000 m in elevation, and do not have a conspicuous alpine flora (e.g., Martínez et al., 2017).

Climatic Variation

The climate of the dry temperate Andes is arid or semiarid. The elevated part of this region corresponds with the Southern Andean Steppe Ecoregion (Olson et al., 2001; Ezcurra, 2001). Snowstorms, hailstorms and frosts are frequent year-round in these high montane regions. Precipitation in the central and southern regions falls mostly in winter, driven by winds from the Pacific, whereas in the northeast part of the DTA the precipitation pattern is affected by winds from the Atlantic and tends to fall in summer. Mean annual precipitation varies from north to south, from approximately 200 to 800 mm, and increases with elevation. For example, mean annual precipitation and mean annual temperature in Puente del Inca at 2720 m in Mendoza (in the central part of the region) is 342 mm and 7.4°C respectively (Cabrera, 1976). Precipitation levels tend to decrease from west to east, especially in the center and south of the dry temperate Andes.

Further south, the climate of the wet temperate Andes is generally wetter. The region corresponds with the Maule, Valdivian and Magellanic subpolar forest ecoregions (Olson et al., 2001). Strong, humid winds blow from the Pacific year-round, especially in winter and spring, resulting in high levels of rainfall. The highest precipitation levels are found between about 40°S and 44°S, and decrease toward the South. For instance, the average annual precipitation is >3000 mm in Peulla at the latitude of Mount Tronador (approx. 41°S), while it is <1000 mm in the mountains near Ushuaia (approx. 55°S). In addition, the southern Andes intercept the humid westerlies that blow from the Pacific Ocean, producing a rain-shadow effect that results in a steep west-east precipitation gradient. Therefore, annual precipitation levels in alpine areas also vary from west to east, e.g., from >3000 mm to the west of Mount Tronador (71°53'W), to approx. 1000 mm near Mount Meta (71°24'W), i.e., within <50 km distance (Ferreira et al., 1998a). At this latitude, temperatures at 1955 m in Mount Catedral vary from a mean of 8°C in the summer months to a mean of -2.8°C in the winter months (Wardle et al., 2001). In the wet temperate Andes, temperature decreases with elevation but also with latitude in a complex way, with a lapse rate of approximately 0.6°C/100 m altitude and 0.8°C/degree of latitude, as seen in other mountains (Wardle et al., 2001).

Due to climatic distinctions and the difference in composition of the alpine floras of the DTA and the WTA, they have been classified as belonging to two different phytogeographic districts of the high-Andean biogeographic Province (*Provincia Altoandina*: Cabrera, 1976, Cabrera and Willink, 1980). The *Cuyano* district (in reference to the region of Cuyo, which comprises the provinces of Mendoza, San Juan and San Luis of central Argentina) corresponds with the DTA, and the *Austral* district with the WTA (Cabrera, 1976). In recent biogeographical regionalization of the Andean Region, the former is included as Cuyan High Andean province (Morrone and Ezcurra, 2016), but the latter is not differentiated from the southern biogeographic provinces of the Maule, Valdivian and Magellanic forests. This is probably due to the smaller area occupied by alpine vegetation in the WTA, forming isolated islands restricted to mountaintops surrounded by forest.

Limits of the Alpine Vegetation in the Temperate Andes

Alpine vegetation is mostly defined as that found above treeline on mountains, so in arid areas devoid of forests it is difficult to establish the limits between alpine and subalpine vegetation. In these cases, alpine vegetation is characterized by plant communities without large woody plants (i.e., <3 m, Körner, 1998) that generally coincide with areas with average temperature of the growing season lower than 6.5°C (Körner, 1998; Mark et al., 2001; Körner and Paulsen, 2004). In the Southern Hemisphere, treelines of broad-leaved species such as *Nothofagus* (Nothofagaceae) or *Kageneckia* (Rosaceae), have been found at lower elevations than conifers in the Northern Hemisphere (Wardle et al., 2001; Piper et al., 2006). This has generally been attributed to the idiosyncratic characteristics of these genera, which apparently have different thermal requirements than Northern Hemisphere treeline genera such as *Pinus* (Mark et al., 2001; Körner and Paulsen, 2004; Piper et al., 2006). In New Zealand (Wardle, 1965) and South America (Ezcurra & Gavini pers. obs.), specimens of the exotic *Pinus contorta* from North America can spread to elevations that are higher than the natural *Nothofagus* treelines. Therefore, alpine areas of the temperate Andes can be considered to generally correspond with high altitude areas that have growing season temperatures below ca. 9.5°C (Körner and Paulsen, 2004, Gavini, unpublished, but see Mark et al., 2001 for the latitude of Tierra del Fuego). The area between this line and that of permanent snow is the region considered here as the alpine (Fig. 1B).

Vegetation of the Dry Temperate Andes

The high-Andean vegetation on the Chilean side of the dry temperate Andes is generally found above the mesic forest remnants of *Nothofagus macrocarpa*, *N. pumilio* (Nothofagaceae) and/or *Austrocedrus chilensis* (Cupressaceae), or above more xeric Mediterranean matorral with small trees of *Kageneckia angustifolia*. There is an altitudinal zonation with a lower belt dominated by large shrubs, an intermediate belt represented by small shrubs, tussock grasses and cushion plants, and a high, subnival, desert belt with small forbs, rosettes and small-sized grasses. These belts have been given different names, mostly Sub-Andean, Lower Andean and High Andean, or *Piso Subandino*, *Piso Andino Inferior*, and *Piso Andino Superior* (e.g., Squeo et al., 1994; Muñoz-Schick et al., 2000). At the latitude of Santiago, Chile, shrubs such as *Chusquea oppositifolia* and *Nassauvia axillaris* are representative of the lower belt (approx. 2000–2700 m), cushion plants such as *Azorella madreporica* and *Laretia acaulis* characterize the intermediate belt (approx. 2700–3300 m), and *Nassauvia lagascae*, *Oxalis erythrorhiza*, *Nassauvia pinnigera* and *Moschopsis leyboldii* occur in the high Andean desert (approx. 3300–3900 m). There are also areas with tussock grasses of the genus *Pappostipa* termed “coironales,” generally growing in places with less pronounced slopes (Muñoz-Schick et al., 2000). In humid or wet sites, species-rich bog communities termed “*vegas*” develop, dominated by Juncaceae, Cyperaceae and grasses. These latter areas can become overgrazed by domestic livestock, especially goats that are taken to these sites in summer (Chiapella and Ezcurra, 1999).

At different latitudes on the Argentinian side, the high Andean plant communities of the DTA grow above the Monte desert vegetation dominated by *Larrea* species (e.g., Méndez, 2004) or above the Patagonian steppe (Chiapella and Ezcurra, 1999). These communities vary in relation to elevation, humidity, continentality, slope angle, slope aspect and soil type. This is the reason why vegetation belts cannot be clearly delimited here (e.g., Chiapella and Ezcurra, 1999; Méndez, 2004; Méndez et al., 2006). However, the pattern is somewhat similar to that of the Chilean side, with three vegetation belts that are given different names, generally a lower belt of tussock grasses, mostly of *Pappostipa*, together with large shrubs of *Adesmia*, *Mulinum*, *Nassauvia* and *Chusquea* at lower elevations (approx. 1900–2700 m). This belt has sometimes been described as “*región de la leña amarilla*” due to the yellow color of the branches of *Adesmia pinifolia*, a conspicuous large shrub that sometimes grows taller than 2 m in the area. At intermediate elevations (approx. 2700–3300 m), small shrubs and cushion plants dominate, e.g., *Oxalis*, *Junellia*, *Adesmia*, *Laretia* and *Azorella*. This belt has been described as “*región de la llareta*,” the common name given to dense woody cushion plants in the area. On the highest belt (approx. 3300–4500 m), especially adapted perennial forbs of genera such as *Senecio*, *Nassauvia*, *Chaetanthera*, *Draba*, *Barneoudia*, *Leucheria*, and *Moschopsis* withstand the extreme insolation, wind and cold found on the denuded, rocky terrain or on unstable scree slopes. In areas with wet soils and near streams, Cyperaceae and Juncaceae dominate, with some genera forming dense and hard cushions such as *Oxychloe* and *Patosia*, together with beautiful large-flowered forbs such as *Mimulus*, *Euphrasia* and *Senecio* species. In these wet environments, bryophytes are also frequent (e.g., Méndez et al., 2006).

Vegetation of the Wet Temperate Andes

The WTA are characterized by the presence of *Nothofagus*-dominated forests on their slopes. These forests, composed of *N. pumilio* at tree-line (or *N. antarctica* in tree-lines of the most arid and extreme situations) reach approximately 2200 m elevation in northern Neuquén and Bío Bío (37°S), but only attain 500–600 m elevation in Tierra del Fuego (approx. 55°S), as latitude increases (Mark et al., 2001; Wardle et al., 2001). Near treeline, these tree species form prostrate *krummholz*. Above these forests, alpine vegetation appears on mountaintops in the archipelago of open terrain.

Altitudinal zonation is not clear in the WTA. The lower alpine belt is generally characterized by a relatively high cover of small shrubs such as *Gaultheria pumila*, *Empetrum rubrum* and *Baccharis magellanica* (Roig, 1998; Ferreyra et al., 1998a; Mark et al., 2001). The strong precipitation gradient from west to east results in important differences in humidity and duration of snow-cover in different mountains that result in marked differences in plant composition and species richness (Ferreyra et al., 1998a,b). Studies on mountains along precipitation gradients at different latitudes of the WTA have shown an increase of richness from west to east and from higher to lower latitudes (Arroyo et al., 1989; Ferreyra et al., 1998a; López-Angulo et al., 2018). In addition, on a given mountain, the altitude, wind exposure, slope, and aspect contribute to determine different levels of species richness, vegetation-cover and life-form spectra. The temperature gradient determined by altitude, and the humidity gradient determined by solar radiation and wind exposure that relate to slope aspect produce marked differences in community composition and richness on mountains (Ferreyra et al., 1998a; Mark et al., 2001).

At the latitude of Nahuel Huapi National Park, Argentina, in the northern WTA, a rich alpine flora has been recorded, with > 230 species (Ferreyra et al., 1998b). The western sector with higher precipitation harbors fewer alpine species (~149) than the drier eastern sector (~220). Lower species richness in mountains with higher precipitation has also been observed in the southern WTA. In Sierra de los Baguales, Chile, 349 species were recorded for alpine and subalpine vegetation, varying from 252 species of plants on Mount Santa Lucía in the east to just 53 species on Mount Daudet in the west (Arroyo et al., 1989). These differences have been attributed to a shorter growing season in the west, due to a longer duration of the snow-cover and the higher levels of precipitation, and also to historical effects that persist from the last glaciation (Arroyo et al., 1989; Ferreyra et al., 1998b).

Plant communities along the margins of streams and in wet meadows (termed *mallines* in this area) are dominated by Cyperaceae and Juncaceae (e.g., *Carex*, *Oreobolus*, *Marsippospermum*), mixed with bryophytes and forbs with showy flowers of genera such

as *Calandrinia*, *Caltha*, *Senecio* or *Primula*. Some dwarf shrubs such as *Azorella lycopodioides* form dense cushions on these wet soils. The diversity of the alpine plant communities of these wet places, together with that of drier sites, contributes to the overall high species richness of the alpine areas of the eastern mountains of the wet temperate Andes.

Diversity of Life Forms

Plants of the high montane regions of the temperate Andes have considerable adaptations to the particularly diverse, harsh environments. During the winter the plants remain covered by snow for many months, and during the summer they can withstand extreme cold, heat, wind, and desiccation within a single day. The main life forms of alpine plants of the temperate Andes are perennial forbs (Fig. 2), tussock grasses, cushions and shrubs (Fig. 3). Annual herbs are very rare, and only appear in the lower sub-Andean belt of the DTA (Squeo et al., 1994). At higher elevations, many plants grow close to the ground and form flat cushions or dense mats that withstand the wind and cold temperatures (e.g., *Oreopolus glacialis*, *Oxalis erythrorhiza*, *Azorella monantha*). Perennial forbs can form rosettes that can be wide and flat (e.g., *Pachylaena atriplicifolia*, *Gamocarpha scapigera*, *G. ventosa*) or more or less cylindrical and vertical (e.g., *Nassauvia revoluta*, *Chaetanthera spathulifolia*, *Viola columnaris*), and frequently have deep rhizomes or taproots and fleshy leaves (Fig. 2). These latter plants sometimes mimic the shape of stones, probably as an anti-herbivory defense, but are very conspicuous in flower. The rigid, cylindrical growth-form is probably an adaptation to the deposition of sand and ash from frequent volcanic eruptions throughout the Cenozoic. Rocks, as well as tussock grasses and cushion plants (Fig. 3), protect softer and smaller forbs from the cold and the wind, and in some cases rich associations of different species are formed (Cavieres et al., 1998; Nuñez et al., 1999). Forbs such as *Chaetanthera spheroidalis* (Asteraceae) and *Moschopsis leyboldii* (Calyceae) in the DTA, or *Senecio portalesianus* (Asteraceae) and *Nassauvia lagascae* in the WTA, reach the highest elevations (Squeo et al., 1994; Chiappella and Ezcurra, 1999; Ferreyra et al., 1998b; Mark et al., 2001).

Abiotic Determinants of Alpine Plant Diversity of the Temperate Andes

Climate is an important determinant of large-scale biodiversity patterns. Mean annual temperature and precipitation have been shown to be the two most important predictors of species richness in mountains at global and regional scales (Antonelli et al., 2018). Both low temperatures and aridity can be limiting factors in mountain environments. In the DTA, species richness increases toward the south with the increasing winter precipitation (Arroyo et al., 1988; Squeo et al., 1994). On the other hand, richness and plant cover have been observed to more-or-less peak at middle alpine elevations, where conditions are intermediately dry and cold, especially in the north of this region that receives summer precipitation (Arroyo et al., 1988).

In the WTA, steep climatic gradients are generated over short distances. The strong precipitation gradient determined by the rain-shadow effect of the Southern Andes on the westerlies, together with the temperature gradients produced by elevation and slope aspect, result in a mosaic of environments, i.e., relatively wet and warm, wet and cold, dry and warm, and dry and cold. These can be observed in different parts of a mountain, and among different mountains at the same latitude. For example, on three mountains along a west-east transect at 41°S in Nahuel Huapi National Park, Argentina, in the north of the WTA (Mounts Tronador, Lopez, and Meta), annual precipitation varies from ca. 3000 mm in the west to <1000 mm in the east. The relationship between environmental and floristic variation was analyzed in the alpine areas of these mountains using ordination methods (Ferreyra et al., 1998a). In order of importance, longitude, elevation and aspect were the major determinants of floristic variation, resulting in two main vegetation gradients. The first gradient is related to moisture availability, primarily determined by precipitation (related to longitude) and secondarily to variation in wind exposure (west vs. east aspect). The second gradient is related to variation in temperature, primarily determined by elevation, and secondarily by differences in insolation (north vs. south aspect). The great climatic heterogeneity found in this alpine area correlates with an exceptionally high species richness. Average richness within 10 × 10 m plots varied from 9 to 21 species, with higher richness in the relatively drier plant communities with less snow and a longer growing season (Ferreyra et al., 1998a). In 20 surveyed mountains of Nahuel Huapi National Park, a total of 232 alpine species, representing 111 genera and 48 families of vascular plants, have been identified (Ferreyra et al., 1998b). The region of Nahuel Huapi corresponds

to latitudes with the highest precipitation levels of the whole temperate Andes, and the steep precipitation gradient within the National Park results in exceptional regional environmental variation and related plant diversity.

A study of alpine vegetation in higher latitudes, i.e., in the southernmost WTA in the Martial Mountains near the city of Ushuaia (approx. 55°S) found only 80 species (Mark et al., 2001), i.e., a much smaller number. In this area, high-Andean vegetation occurs above *Nothofagus pumilio* forests and *N. antarctica* krummholz with the treeline at ca. 600 m and mean annual precipitation about 600 mm. Here also, major determinants of floristic variation were elevation, aspect, and related temperature (Mark et al., 2001). Species richness decreased significantly with elevation, and was generally higher on the warmer north aspects. Of all the alpine life forms, chamaephytes, i.e., dwarf shrubs, especially the cushion form, were shown to increase in importance with elevation, except at the highest elevations (Mark et al., 2001). A recent large-scale study of plant richness variation at different latitudes in the temperate Andes has provided important insights into the determinants of high mountain plant diversity in this region (López-Angulo et al., 2018). Alpine plant communities were surveyed at three sites, at two latitudes of the DTA with Mediterranean climate and a more- or- less marked summer drought (at 33°S and 35°S), and at a higher latitude in the WTA where drought is negligible, and temperatures are lower (at 51°S). The first two sites of the DTA have treelines of *Kageneckia angustifolia* at 2200 m, and of *Nothofagus antarctica* and *Austrocedrus chilensis* at 1700 m, respectively, with annual precipitation of about 900 mm. The southernmost site has a treeline of *Nothofagus pumilio* at 500 m and annual precipitation of 900–1000 mm. At each site, environmental (standardized elevation, slope, and aspect) and soil characteristics, species richness and cover, and plant-plant interactions were determined at different scales (20 × 20 m plots, 2.4 × 2.4 m quadrats, and 30 × 30 cm cells).

This study showed that species richness ranged from 12 to 50 species per plot, with a mean of 25 species, and was highest in the southernmost, wetter site, whereas beta-diversity among plots (i.e., differences between sites in species assemblages) was lowest there. In all sites, the number of species was higher toward intermediate elevations above treeline, with decreased richness toward the lower and upper alpine limits, while beta-diversity was found to decrease monotonically with elevation. The decrease in richness in the DTA in relation to the WTA, contrary to the well-documented latitudinal decline in species richness toward the poles, was attributed to the intense summer drought found in the DTA that does not exist in the WTA (López-Angulo et al., 2018). The unimodal increase in richness with alpine elevation in all three latitudes of the temperate Andes, i.e., higher values at middle elevations above treeline (Fig. 4), was related principally to the effect and prevalence of positive plant-plant interactions at intermediate elevations (López-Angulo et al., 2018). Therefore, patterns of diversity in the temperate Andes can be attributed to large-scale abiotic (climatic) variables, as well as to smaller-scale biotic interactions.

Biotic Determinants of Alpine Plant Diversity of the Temperate Andes

Biotic interactions, more commonly known as the role of cooccurring species, can also be important drivers of biodiversity. Competition, predator–prey and symbiotic relationships are all classic examples of different types of interactions between living organisms. Particularly, biotic interactions are the effects that one organism have on another, whether these effects are negative or positive. However, the outcome and the magnitude of those effects are known to strongly depend on the environmental conditions (Callaway et al., 2002). This environment-dependence of biotic interactions has been formalized as the “Stress Gradient Hypothesis” (Bertness and Callaway, 1994). This hypothesis postulates that under more benign conditions, negative interactions (i.e., competition) prevail, whereas under high environmental stress and disturbance conditions, positive interactions become more frequent

Fig. 4 Relationship between species richness and elevation across different latitudes of the temperate Andes. Species richness along an altitudinal gradient in the wet temperate Andes (blue) and in two latitudes of the dry temperate Andes: with shorter dry season (green) and longer dry season (orange). Solid lines when the main environmental stressor is low temperature; dotted lines when summer drought (orange), facilitation (blue), or both mechanisms (green) act to modulate the original monotonic pattern. Modified from López-Angulo et al., 2018.

and important (Bertness and Callaway, 1994; Callaway et al., 2002). In the latter context, positive interactions are usually referred as “facilitation” since, in general, one organism or species receives benefits and the other is neither harmed nor benefited.

Alpine ecosystems represent highly stressful environments for organisms. For instance, plants must cope with extremely low temperatures, short growing seasons, excessive radiation levels, strong winds, nutrient-poor soils, unstable substrates as a result of local avalanches, and the runoff associated with melting snow (Körner, 2003). Cushion plants are, however, one of the life-forms best adapted to these severe high mountain ecosystems. In particular, the short stature and compact shape of cushion plants allows them to decrease the wind abrasion, buffer the extreme temperatures, and soils below cushions usually retain more water and nutrients than the surrounding bare ground (Arredondo-Núñez et al., 2009). In this way, cushion plants modify the suitability of the abiotic environment. This is the reason that cushion plants are widely recognized as “nurse plants”. Nurse plants are organisms that facilitate the establishment, growth and/or survival of other less-stress tolerant organisms by offering microhabitats more favorable than the surrounding environment (Callaway, 2007). Indeed, several studies have reported the presence of other species of plants growing within cushion plant patches. This process is the classic type of facilitation in which the positive effects of neighbors buffer others from the stressful conditions.

Facilitation is a highly ubiquitous phenomenon that occurs in all alpine regions of the world (Cavieres et al., 2016), and high-Andean communities are no exception. Numerous small-scale observational and experimental studies performed in the Andes have revealed the importance of cushion plants on alpine plant diversity. For instance, in the Patagonian Andes, Nuñez et al. (1999) showed that patches dominated by cushions of *Mulinum leptacanthum* (Apiaceae) and *Oreopolus glacialis* (Rubiaceae) harbor a greater number of species than patches without cushion plants. Consistently, studies in the alpine communities of central Chile found that between 30 and 50% of plant species grow more frequently inside cushions than outside of them (e.g., Cavieres et al., 1998, 2002, 2006; Badano et al., 2002; Arroyo et al., 2003; see Arredondo-Núñez et al., 2009). Furthermore, the dependence of several plant species to the presence of cushion plants typically increases with the elevation, because environmental stresses also increase. Nonetheless, as indicated by some empirical studies, this is not always the case (e.g., Cavieres et al., 2006; Cavieres and Badano, 2009), suggesting that it is not yet clear how facilitation varies through gradients of environmental stress.

In South America, mainly in the Andes of Chile, much research has been performed on the so called “genetic” cushion plant species. These are species that, regardless of environmental conditions, always adopt the cushion life-form. Notable species include *Bolax gummifera*, *Laretia acaulis*, *Azorella monantha* and *Azorella madreporica* (Apiaceae). These are all well-studied species of cushion plants in the Chilean Andes (e.g., Cavieres and Badano, 2009; Arredondo-Núñez et al., 2009). *Mulinum leptacanthum* and *Oreopolus glacialis* are the most common and well known cushion plants from the Argentinian Andes (Nuñez et al., 1999). Hence, broadly speaking, species of Apiaceae (Umbelliferae) seem to be the most common cushion plants across the southern Andes (Fig. 5). However, far less attention has been given to species that we define here as “facultative” cushion plants. In contrast to the aforementioned cushion plants, these plants are herbs, tussocks, or prostrate shrubs whose life-forms occasionally shift to cushion-like patches, a change that could be driven by the extreme environmental conditions. Accordingly, these facultative cushion plants can also act as nurse plants. Some examples from the Argentinian Andes are *Acaena* (Rosaceae), *Senecio* (Asteraceae) and *Gaultheria* (Ericaceae) (Fig. 5).

Most studies have assessed the facilitative effects of Angiosperm cushion plant species, even though the ecological role as a nurse plant is not necessarily exclusive to this taxonomic group. In fact, bryophytes may excel as nurse plants. Particularly, mosses are the dominant ground cover in a wide array of ecosystems, especially in those developing under extreme cold-humid environments such as alpine ice-melting forelands (Fig. 6). Consequently, mosses may influence the performance and distribution of other plants. Like many vascular plants with a cushion growth form, mosses can provide better microhabitats than the surrounding environment by increasing soil moisture and nutrients, by also reducing the frost damage experienced by seedlings and plant roots, and buffering the extreme temperatures that affect the surrounding bare ground (Carlsson and Callaghan, 1991; Gold and Bliss, 1995; Groeneveld and Rochefort, 2005; Groeneveld et al., 2007; Roberts et al., 2009). Hence, the microenvironment provided by mosses can also enhance the establishment, growth and/or survival of other plant species (Carlsson and Callaghan, 1991; Groeneveld et al., 2007; Casanova-Katny and Cavieres, 2012). Consistent with some studies done in the Polar tundra, recent research performed in alpine ice-melting forelands in the northern Patagonian Andes showed that several species of vascular plants settle and grow within species of cushion-forming mosses (Gavini, unpublished), like *Philonotis esquelensis* (Bartramiaceae), *Bryum pseudotriquetrum* (Bryaceae), and *Bartramia patens* (Bartramiaceae) (Fig. 6). Therefore, moss-cushion patches can sustain higher species richness and plant abundance in comparison with bare ground and rocky areas, a similar pattern as that found for angiosperm cushion-plant species.

Origin of the Alpine Flora of the Temperate Andes

Alpine floras generally originate from a mix of local ancient Tertiary elements, immigrants from several sources, and new evolutionary lineages (e.g., Körner, 2003). Andean orogeny is considered one of the most important drivers in the development of plant diversity in South America. A recent work compared available phylogenetic studies and divergence time estimates for plant lineages that may have diversified in response to Andean orogeny. Divergence time estimates indicate that most high-elevation lineages originated and diversified during or after the major phases of Andean uplift (Mid-Miocene to Pliocene). As expected, Andean mid-elevation lineages tend to be older than high-elevation groups (Luebert and Weigend, 2014), suggesting a relatively modern origin for the much of high Andean flora.

(Note several species found growing inside cushion patches). Photographs by Sabrina Gavini.

Dispersal along the Andes has been shown to occur in either north or south directions, mostly after the Andean uplift (Luebert and Weigend, 2014). However, Doan (2003) proposed a general south-to-north diversification pattern for plants and animals based on the earlier uplift of the Southern Andes in the early Miocene. In fact, evidence of this has been found for several plant genera, including *Azorella*, *Chuquiraga*, *Oreobolus*, *Ourisia* and *Perezia* (Luebert and Weigend, 2014 and lit cit. there). Work based on Miocene fossils (Palazzesi et al., 2012) also reconstructed a northward displacement of an originally south-temperate floristic element, coinciding with climatic cooling, eastern Patagonian aridization and Andean uplift. This northward displacement of various lineages of southern South American plants during the colonization of the Andes was likely the result of niche conservatism. Limited climatic tolerances to decreasing temperatures probably led to northern shifts of distributions, as species tracked their fundamental climate niches through space (Palazzesi et al., 2012). Therefore, the temperate Andes and other high-latitude elevated areas of southern South America appear to have been important in the origin of alpine floras of lower latitudes of the continent. The close relationship between the floras of Patagonia, the High Andes, and the Puna has long been observed (Cabrera, 1978). Nevertheless, the history of the high Andean flora is complex and plant diversification surely has been driven by a variety of processes, including Andean orogeny, but also environmental changes and biotic interactions (Luebert and Weigend, 2014).

Current Conservation Status

Alpine regions of the temperate Andes have several more-or-less protected areas throughout their entire length, so there has been relatively little anthropogenic habitat loss to affect biodiversity conservation. The alpine areas are not seriously threatened by habitat conversion, even though some high-Andean species have traditionally been used as medicine, as fodder, and for fuel (Squeo et al., 1994; Chiapella and Ezcurra, 1999; Méndez et al., 2006). However, mining activities and a marked increase in ecotourism and

Fig. 6 Mosses forming cushions facilitating other species. Alpine ice-melting communities (A) Cerro Hielo Azul (Chubut, Argentina) and (B) Cerro Lopez (Rio Negro, Argentina) where (C, D) moss-cushion patches can be found facilitating angiosperm species. Photographs by Sabrina Gavini.

mountain sports such as climbing or skiing can be observed on several major mountains of the region. These human disturbances may cause problems, such as introductions of exotic species, littering, erosion, sewage disposal and the cutting of woody vegetation for fires. Protected mountain areas with limited prior human use are quite vulnerable to the invasion of exotic plant species because of their popularity as mountaineer destinations (Barros and Pickering, 2014). Burning of shrubs for fuel is common among local herdsmen (Squeo et al., 1994) and is probably an activity that started in ancient times, surely performed by native hunters and gatherers before European settlement. But if this activity increases it could affect the vegetation of the region (e.g., Chiapella and Ezcurra, 1999; Méndez et al., 2006). Although the vegetation is also probably adapted to grazing by native camelids such as vicuñas (*Vicugna vicugna*) and guanacos (*Lama guanicoe*), the relatively recent introduction of exotic ungulates, especially goats (Squeo et al., 1994) and pack animals (Barros and Pickering, 2014), can also have an important impact, especially in the fragile humid ecosystems (Chiapella and Ezcurra, 1999; Méndez et al., 2006; Barros and Pickering, 2014).

Conclusions

Many biogeographic studies have shown a decreasing trend in species richness with latitude and elevation at large scales, which can be attributed in part to space availability, biotic processes, and past evolutionary history, but mostly to an increase in climatic harshness due to temperature decrease (e.g., McCain and Grytnes, 2010). Additionally, the latitudinal and altitudinal temperature gradient can interact with precipitation gradients, resulting in unexpected patterns. In general, climate models predict a decrease in diversity with elevation on humid mountains, and a unimodal diversity pattern on arid-based mountains (Arroyo et al., 1988; McCain and Grytnes, 2010). In addition, at finer scales, other abiotic factors can alter large-scale patterns, such as aspect or slope that determine differences in solar radiation and snow duration, as well as soil characteristics (e.g., Ferreyra et al., 1998a; Mark et al., 2001). All these abiotic factors have been shown to be important determinants of alpine plant diversity in the temperate Andes.

In recent years, several tools have been developed to help quantify and analyze the magnitude of facilitative interactions, e.g., to assess for the effects of cushion plants at the species or community-level (Cavieres and Badano, 2009; Cavieres et al., 2016). Despite current knowledge, more research is needed to unravel the potential ecological and long term evolutionary consequences of biotic interactions in alpine ecosystems. For instance, it has recently been found that biotic interactions can play an important role as evolutionary drivers of alpine plant diversity (Gavini et al., 2019). In particular, both negative (i.e., competition) and positive (i.e., facilitation) interactions can be equally important ecological forces in promoting diversification of alpine plant lineages world-wide, challenging the assumption that only large-scale abiotic phenomena like climate, geomorphology and historical

processes (Körner, 2003) regulate alpine plant diversity. In sum, there is an overwhelming body of evidence indicating that biodiversity in the extreme-cold alpine environments of the temperate Andes is also sustained through biotic interactions, mainly owed to the nurse effect exerted by several unrelated lineages of plants.

Abstract

New Zealand harbors the most significant alpine ecosystems in the Southern Hemisphere outside of South America, with a biota characterized by high levels of endemism. However, NZ's alpine areas are geologically recent and tectonically highly active, which has led to allopatric speciation and many poorly understood species complexes among plants, invertebrates and reptiles. NZ's alpine biota has had to adapt to climatic unpredictability so possibly may be less affected by future climate change. The greatest threats to NZ alpine ecosystems are invasion by introduced pest species, most notably cold tolerant conifers, ungulates, and rodents.

Origin of the New Zealand Alpine Zone

New Zealand is a long, narrow, topographically diverse archipelago with 58% of the landmass above 250 m altitude and 22% of the largest island, South Island, above 1000 m altitude (Salinger, 1988). The three main islands, North, South and Stewart, cover a latitudinal range from 34.42°S at the northernmost tip of North Island to 47.28°S at the southernmost point of Stewart Island. Alpine ecosystems, defined as the regions between actual or reconstructed timberline and permanent snow line, cover c. 30,000 km², or approximately 11% of New Zealand (Halloy and Mark, 2003). These alpine areas owe their existence to New Zealand's position on the boundary of the Pacific and Australian plates. The Kaikoura orogeny, which commenced c. 25 million years ago, uplifted a spine of mountains along this plate boundary, with a single Alpine slip fault (Fig. 1) bounding their western edge through the central South Island (Fitzsimons and Veit, 2001). Named the Southern Alps for their resemblance to the European Alps, these mountains support the largest area of alpine ecosystems in New Zealand. However, these alpine areas are geologically young, resulting from accelerated uplift over the last 5 million years, combined with a cooling climate (Heenan and McGlone, 2012). Rates of uplift of the Southern Alps are still high, 5–8 mm/year, but are counteracted by high rates of erosion associated with easily fractured basement sedimentary greywacke, earthquake-triggered landslides and extremely high orographic precipitation (Fitzsimons and Veit, 2001). Due to these high rates of erosion, New Zealand's alpine areas do not reach the heights of Northern Hemisphere temperate mountains, for example the highest peak, Aoraki/Mt. Cook (Fig. 2) is only 3724 m above sea level (2014 survey), having lost 40 m since 1991 from rockfall and slips (Sirguey, 2014). Alpine areas in New Zealand's North Island are also geologically young but much smaller in extent, with some ranges relating to North Island fault systems (Fig. 1). The largest alpine areas in North Island are associated with the Taupo volcanic complex, which commenced andesitic activity c. 2 million years ago and is the most frequently active and productive silicic volcanic system on Earth (Wilson et al., 1995). Alpine vegetation also occurs sporadically at lower-than-expected altitudes on infertile or water-logged soils exposed to harsh winds, for example Mt. Moehau (892 m) in northeastern North Island (Fig. 1) and at sea-level in Stewart Island.

Habitat Types

The alpine zone commences at lower altitudes in New Zealand compared with similar northern latitudes as a result of New Zealand's strongly oceanic climate. Tree species grow to more than 4500 m at c. 35°N latitude in Tibet and to over 3000 m at c. 47°N (Miehe et al., 2007). In contrast, treeline in New Zealand varies from 1400 m in central North Island (39°S) to 900 m in south-western South Island (46°S) (Mark and Dickinson, 1997). In much of South Island, low diversity southern beech forest (family Nothofagaceae) gives way abruptly to a low alpine zone of tall grassland dominated by the near endemic tussock (bunchgrass) genus *Chionochloa* (Poaceae; Fig. 3). In parts of the country lacking southern beeches, such as the "beech gap" in central South Island, and Mt. Taranaki, western North Island, southern conifers (family Podocarpaceae) and tall subalpine shrubs in the Asteraceae and Ericaceae families grade into tall tussock grassland (Mark, 2012; Cieraad and McGlone, 2014; Wardle, 2008). The

Fig. 1 New Zealand alpine regions, showing major fault lines and key locations mentioned in the text. Alpine areas based on Fisher, F.J.F. (1965). dominance of tall tussock-forming grasses and large-leaved, evergreen herbaceous plants in New Zealand's low alpine ecosystems differentiate them from temperate alpine areas of the Northern Hemisphere. Instead, these ecosystems more closely resemble alpine ecosystems of tropical high mountains that, like New Zealand, can experience as much temperature variation during diurnal cycles as between seasons (Mark et al., 2000).

The distribution of habitat types in the alpine zone most commonly relates to slope stability, soil development and winter snow cover (Mark and Dickinson, 1997; Lord et al., 2018). Due to the youth of New Zealand's mountains and the highly dynamic tectonic environment, soils are generally weakly developed, and highly mobile areas of rocky talus, or "scree," as they are known locally, are common in the steep, fractured mountains of central South Island (Figs. 2 and 4). These scree environments are home to a specialist set of plants from a range of families that produce robust, long lived roots that grow downslope, and are often attached only loosely to small aboveground rosettes (Dawson, 1988). These plants are often highly cryptic, at least to human eyes (Fig. 5). On stable rock, the sparse vegetation features a number of spectacular hummock-forming plants in the Asteraceae family, known locally as "vegetable sheep." This growth form has parallels with the giant *Azorella* cushions of high altitude South American deserts which have been shown to buffer internal tissue temperatures against extreme diurnal temperature fluctuations (Kleier and Rundel, 2009).

Below permanent snow line, which decreases from 2400 m in central North Island to 2000 m in southern South Island (Mark and Dickinson, 1997), winter snow depth and length of snow cover is strongly affected by the interaction between topography and prevailing wind flow. Snow tends to be deposited by cold, wet, south-westerly weather systems and redistributed during gusty,

Fig. 2 Aoraki/Mt. Cook, with Hooker Glacier in the middle distance and Mueller Glacier moraine in the foreground, Canterbury.

north-westerly anticyclonic periods, leading to marked west-east gradients in rain and snow fall, especially across central and southern South Island. Annual precipitation exceeds 4 m for exposed mountains in the North Island and can exceed 10 m on the western slopes of the Southern Alps. Isolated alpine ranges in the rain shadow-affected eastern South Island, such as Rock and Pillar Range (Fig. 1), are significantly drier but still receive more than 1000 mm annual precipitation. On these ranges, redistribution of snow results in a largely snow-free summit plateau, while late-lying snow banks up to 7 m deep accumulate in eastern (leeward) gullies (Fig. 6), and in some seasons do not thaw completely in summer (Lord et al., 2018). The timing of snowmelt is critically important to flowering phenology in these snowbanks, with many species forming floral apices in autumn, enabling rapid flowering in spring even as the snow is receding (Mark, 1970). This marked variation in snow depth and duration, combined with strong winds (averaging more than 6 m/s, and gusting up to 17.4 m/s), and frequent frosts year round, leads to a vegetation gradient from summit cushionfield, dominated by lichens and ground-hugging dwarf shrubs and herbs, through grassy herbfield on leeward slopes under moderate snow cover, to highly speciose snowbank communities in wet, leeward gullies (Lord et al., 2018; Bliss and Mark, 1974).

Flora and Fauna

The vascular flora of New Zealand's alpine ecosystems (species which occur above timberline, regardless of whether they are restricted to alpine areas) currently consists of more than 750 species, subspecies, and varieties (Table 1) representing as much as 30% of the native flora of New Zealand. While about 93% of alpine plant species are endemic to New Zealand, plant endemism is very low at the genus level, with many genera shared with Australia, South America, and South Africa (Mark, 2012). Many species, or their close relatives, also occur in cold, wet infertile areas at lower altitudes, suggesting colonization of the newly uplifted alpine areas by preexisting lineages (Heenan and McGlone, 2012), followed by allopatric speciation on mountain ranges isolated during Pleistocene interglacials (Winkworth et al., 2005). Molecular studies in speciose alpine genera (e.g., the *Veronica* complex (*Hebe*, *Parahebe*, *Chionohebe*, *Hebejebbie*), *Myosotis*, *Ranunculus*, *Chionochoa*) show rapid morphological diversification in the last 1–3 million years, but low genetic differentiation, leading to poor phylogenetic resolution for many genera, hybridizing or

Fig. 3 *Chionochloa* tussock grassland, Dunstan Range, Otago.

intergrading species complexes and a high prevalence of polyploids (Murray and Lange, 2011; Pirie et al., 2010; Lockhart et al., 2001; Winkworth et al., 2005; Wagstaff and Garnock-Jones, 1998; Meudt et al., 2015). Speciation in some groups is related to edaphic specialization; the endemic alpine rockcresses, *Pachycladon* (Brassicaceae), show a pattern of basal generalist species and radiation of specialists on particular rock types (Heenan and Mitchell, 2003). Species diversity also differs markedly between alpine regions, with high levels of endemism in the so-called “endemism centers” of the south-west and north-west of South Island, but lower levels in central South Island and North Island alpine ecosystems (McGlone, 1985). A number of alpine plant taxa also show disjunct distributions between South Island endemism centers (Clarke et al., 2018). In North Island this low level of endemism is likely related to frequent volcanic activity (McGlone, 1985). However, the central South Island endemism gap may be more a product of elevated rates of speciation in the more topographically and geological diverse “endemism centers” rather than climatic or tectonic factors (McGlone et al., 2001; Clarke et al., 2018). For example, *Chionochloa* tussocks (Poaceae) show greatest species richness and regional endemism in south-west South Island (5/14 taxa endemic) followed by north-west South Island (3/10 taxa endemic), with many taxa occurring in specialized habitats or on uncommon rock types. Only two of seven species found on North Island are region endemics and the species found in central and eastern South Island are all widespread, but represented by geographically distinct subspecies (Pirie et al., 2010; Edgar and Connor, 2000).

Invertebrate biodiversity is exceptionally high in New Zealand alpine ecosystems, with c. 40% of invertebrate species in the New Zealand Biological Region found in alpine areas and more than 90% of them endemic to New Zealand (Mark, 2012). Many groups show considerable geographic variation and are poorly resolved taxonomically. Unlike northern temperate alpine areas, New Zealand has no native social bees. Instead, small (4–10 mm long), solitary bees in the families Colletidae and Halictidae are found throughout the mountains (Donovan, 2007). There are relatively few butterfly species in New Zealand, although a recent revision indicates considerable allopatric speciation in what were once thought to be single, widespread montane/alpine species (Patrick and Patrick, 2012). Moths, on the other hand, are exceptionally diverse and common in New Zealand, with well over 1650 species, c. 85% of which are endemic (Hoare et al., 2011). Moth diversity is especially high in South Island alpine regions with many taxa yet to be formally described (Mark, 2012; Hoare et al., 2011), and many knowledge gaps concerning host plant relationships (Buxton et al., 2018). Coleoptera are also diverse and common in New Zealand alpine ecosystems, with large, day-active chafer beetles (Scarabaeidae) and weevils (Curculionidae) being particularly conspicuous (Mark, 2012). One of the most spectacular groups of alpine insects are giant (20–80 mm long), flightless Orthopterans in the family Anostostomatidae, known as weta. Two genera in particular, *Deinacrida* and *Hemideina* (Fig. 7), have speciated extensively in South Island montane and alpine environments, following

Fig. 4 Rock talus and scree habitats, Canterbury.

mountain uplift over the last 5 million years (Pratt et al., 2008). Orthopterans in the grasshopper family Acrididae are also speciose and abundant components of alpine ecosystems. Twelve of the 15 species described by Bigelow (1967) are found in alpine grassland and scree habitats. More recent work has indicated several of the most widespread species are in fact unresolved species complexes (Trewick and Morris, 2008). Considerable color variation exists within these species complexes that may at least partly relate to crypsis (Fig. 8).

The alpine avifauna of New Zealand, as with the country as a whole, has suffered numerous extinctions since the arrival of humans (Holdaway, 1989). Subfossil remains indicate that three species of flightless moa (Dinornithiformes) were a component of alpine ecosystems (Worthy, 1990) along with extinct coot and raptor species (Holdaway, 1989). The now critically endangered flightless parrot, Kakapo (*Strigops habroptilis*), was also present in pre-human alpine ecosystems, but is now restricted to managed populations on predator-free islands (Powlesland et al., 2006). While a range of birds, including seabirds such as Black-backed gull (*Larus dominicanus*), utilize alpine areas during summer, the nationally endangered Hutton's shearwater (*Puffinus huttoni*) is the only seabird globally to breed exclusively in an alpine environment, and only the kea (*Nestor notabilis*), and the rock wren (*Xenicus gilviventris*) are true alpine specialists, occurring exclusively in the Southern Alps of South Island (Gaze, 2013; Kemp, 2013). The only naturally occurring wild population of the flightless South Island Takahe is in a low alpine valley in Fiordland, where it feeds on the tiller bases of *Chionochloa* during summer and fern roots below timberline during winter. However, as for Kakapo, subfossil remains indicate that Takahe were once also widespread at lower altitudes (Maxwell, 2013).

New Zealand's only native land mammals, bats, are not known to venture above timberline; the only other vertebrates, apart from birds, that naturally occur in alpine areas of New Zealand are lizards. Four of New Zealand's six lizard genera, approximately a third of currently known gecko species and a quarter of skink species, are found in alpine and montane habitats (Hare et al., 2016). Intensive field survey efforts in South Island mountains since the 1990s have revealed considerably more lizard diversity than previously thought with many more species undoubtedly yet to be discovered (Mark, 2012; Hitchmough et al., 2016). The recently described gecko genus, *Mokopiriakau*, is possibly the most specialist alpine group with several undescribed entities restricted to single mountain ranges. Likewise the common gecko complex, genus *Woodworthia*, contains a number of undescribed, apparently geographically restricted entities (Hitchmough et al., 2016), also suggesting a role for allopatric speciation.

Pollination Biology

The New Zealand alpine flora is remarkable for the prevalence of white flowers (**Fig. 9**), estimated as 78% of large-flowered species by [Cockayne \(1928\)](#), but more accurately around 62% of biotically pollinated species (Lord unpublished data). Unpigmented flowers that appear white to humans, and do not reflect UV, dominate even in groups such as *Veronica*, forget-me-nots (*Myosotis*) and gentians (*Gentianella*) known for their blue-purple flowers elsewhere ([Lloyd, 1985](#); [Campbell et al., 2010](#)). In Northern Hemisphere alpine and arctic regions, blue and purple flower colors are associated with pollination by social bees ([Eidesen et al., 2017](#); [Ishii et al., 2018](#)). As there are no native social bees in New Zealand, the high frequency of white flowers in alpine ecosystems has been linked to the abundance of flower-visiting Diptera ([Ishii et al., 2018](#)). However, New Zealand subantarctic islands that lack even solitary bees, support endemic blue *Veronica* and *Myosotis* species and pink-purple *Gentianella* species ([Lord et al., 2013](#); [Lloyd, 1985](#)). Furthermore, native flies can show color discrimination behavior, whereas native solitary bees often show a preference for white flowers ([Campbell et al., 2010, 2012](#); [McGimpsey and Lord, 2015](#)). While less abundant than flies, solitary bees can be many times more effective pollinators, so may have had a role in the evolution of flower color in the New Zealand alpine ([Bischoff et al., 2013a,b](#)). It is, however, still unclear whether selection by legitimate pollinators is the main, or only, driver of loss of floral pigments

Fig. 8 Number of grasshoppers (*Sigaus australis* complex; Acrididae) of each of three broad color morphs encountered during a 5 min walk through three different alpine habitat types, Remarkables Range, New Zealand. Images show: *Green* (A) and *brown* (B) morphs on rock, and *gray* morph (C) on cushion bog vegetation. Redrawn from Richardson, E. (2011). *Warm or well obscured: Microhabitat selection in the New Zealand alpine grasshopper Sigaus australis*, Postgraduate Diploma in Science Dissertation, University of Otago, New Zealand.

in New Zealand alpine plants. The low fertility of New Zealand's raw, highly leached alpine soils may make pigments costly to produce; pigment expression in flowers, where it does occur, may be more associated with the benefits of anthocyanin production in stressful environments (Campbell et al., 2012). For example, blue coloration due to cyanidin production in the grassland harebell *Wahlenbergia albomarginata* (Campanulaceae) increases with altitude, cold temperatures and drought (Sawrey, 2012; Sawrey and Lord, unpublished data).

Mast-Flowering

Trophic interactions in New Zealand's alpine ecosystems are strongly influenced by large scale variation in productivity driven by mast-flowering species. Mast-flowering or mast-seeding is the phenomenon of synchronized mass reproduction within a species at supra-annual intervals, with intervening years of little or no seed output, and is especially prevalent in the New Zealand flora (Schauber et al., 2002). Alpine snow tussocks in the genus *Chionochloa* include some of the most extreme mast-flowering species in the world; synchronized mast-flowering of co-occurring *Chionochloa* species significantly reduces the proportion of seeds lost to specialist native dipteran and lepidopteran seed predators (Kelly et al., 2000). This pulse in resources also stimulates population increases in introduced mice which switch diet from invertebrates to *Chionochloa* seeds in heavy mast years (Wilson and Lee, 2010). The giant speargrasses (*Aciphylla* species, Apiaceae) also exhibit mast-flowering behavior (Young, 2006; Campbell, 1981), and may play a critical role in the population dynamics of associated flower- and leaf-feeding invertebrates. For example, native flightless speargrass weevils (*Lyperobius* species, Curculionidae: Molytinae) are host specific to Apiaceae, predominantly *Aciphylla*, and show extensive allopatric speciation in alpine areas of South Island. Larvae feed on *Aciphylla* roots, but the adults, which can live 2–3 years, feed on leaves and inflorescences (Craw, 1999). Several *Celmisia* species and other alpine Asteraceae also show mast-flowering behavior (Kelly et al., 2013; Campbell, 1981; Mark, 1970). While levels of seed predation by dipteran larvae do not appear to differ between mast-flowering and regular flowering *Celmisia* species (Spence, 1990), common flower visitors to Asteraceae and *Aciphylla*, such as hoverflies (e.g., *Allograpta* spp., *Platycheirus* spp., Syrphidae), increase significantly in abundance in a heavy mast-flowering year (Miller et al., 2018).

Principal Anthropogenic Stressors and Trends

New Zealand was the last landmass of significant size to be colonized by humans, so there arguably is a much clearer picture of human impacts on alpine ecosystems here, than anywhere else in the world. Ancestors of the indigenous Māori people voyaged from Polynesia around 800 years ago. The high mountains of the new homeland, Aotearoa, came to feature strongly in stories of creation and shaping of the land in both North Island/Te Ika o Maui (Te Ahukaramū, 2006) and South Island/ Te Wai Pounamu/Te Waka o Aoraki (Anon, 2004; Waaka, 2016). Seasonal "mahinga kai" expeditions to inland and alpine areas were not

Fig. 9 A montage of common southern New Zealand alpine plants illustrating the abundance of small white flowers.

only vital for food gathering, but also expressed connection to ancestral beings, kinship, and guardianship of the land (Phillips et al., 2016). In addition to hunting and harvesting activities, the Southern Alps were also crossed by east coast South Island iwi (tribes) in order to obtain the prized pounamu stone (jade) from west coast rivers, that was then traded throughout the country (Brailsford, 1996), hence one of the Maori names for South Island—Te Wai Pounamu. Along the way, expeditioners made use of alpine plants such as tussock grasses and Tikumu (mainly *Celmisia semicordata*) for clothing and insulation (Lord et al., 2010; White and Lord, 2012). Widespread fires were a feature of this period of human exploration (McWethy et al., 2010). These fires likely spread into alpine areas, removing the natural timberline forest in rainshadow-affected eastern South Island. This allowed *Chionochloa* tussock grasses and other alpine species to extend to lower altitudes leading to the formation of extensive tall grasslands in central eastern South Island below climatic timberline (McGlone, 2001).

European explorers did not discover New Zealand until Abel Tasman sighted what was probably the Southern Alps in 1642 (Wilson, 2005). Systematic European colonization of New Zealand from the mid-1800s brought widespread pastoral farming to inland montane and alpine grasslands of South Island, which came to be known as the “High Country.” While much of this land remained in the ownership of the Crown (NZ Government), High Country pastoral leases with perpetual right of renewal gave farmers exclusive grazing rights. Sheep in particular were allowed to freely range to high altitudes over summer periods, initially grazing exclusively on native species. *Chionochloa* tussocks, the structural dominants of alpine grassland show high levels of natural leaf abscission with limited ability to tolerate the browsing style of mammals (Antonelli et al., 2011; Mills et al., 1989). Thus the period of exploitative pastoralism that followed in the mid-late 1800s lead to rapid depletion of palatable native grasses and herbs (O’Connor, 1982). From the 1800s until the 1980s fire was used as a farm management tool to remove plant litter and stimulate new palatable growth of long lived *Chionochloa* tussocks. However, High Country “burn-offs” have become rare in recent times following a reassessment of their impact. Fire stimulates *Chionochloa* tussocks to flower which depletes available growing points, but can be tolerated if occasional or during damp conditions (Payton and Pearce, 2009). However, if fires are frequent or combined with grazing they lead to significant reduction in biomass and ultimate death of these keystone species (Mark, 1994). On some mountain ranges the replacement of tall tussock grassland by shorter unpalatable grasses or cushion plants is thought to be due to intensive burning and grazing (Mark, 1994; Mark and Dickinson, 1997).

Following concerns over declining productivity of high country grasslands, the 1950s saw the start of widespread over-sowing with introduced grasses and legumes (Allan and Chapman, 1989), and along with them the accidental spread of pastoral weeds. While this had little effect on high alpine ecosystems, a subset of these species, particularly *Agrostis capillaris*, *Trifolium repens*, and *Hieracium* species, are now widespread in low alpine ecosystems, particularly in anthropogenic habitats such as road verges, walking tracks and around buildings. Away from human disturbances and in the absence of grazing by introduced mammals, most introduced herbaceous plants seem unlikely to competitively exclude native plants. However, aggressively invasive *Hieracium* species, which can reach the high alpine, are found in areas that have never been grazed by domestic stock; their presence could instead be facilitated by naturalized mammals such as Himalayan Thar (Steer and Norton, 2013). Even though most introduced plants may not be directly competing with native plants, introduced species with open-access flowers such as *Achillea millefolium* and *Hypochaeris radicata* (both Asteraceae), can be highly attractive to native alpine bees and flies, leading to indirect negative effects on native plant reproduction via reduced pollinator services and stigma clogging (Miller et al., 2018). Introduced legumes with long tubular flowers such as *Trifolium repens* and *Lotus corniculatus*, are not attractive to native bees and flies whose tongues are too short to access the nectar (Iwasaki et al., 2018). The spread of these species in New Zealand alpine ecosystems has only been made possible by the availability of introduced long-tongued honey bees (*Apis mellifera*) and bumble bees (*Bombus* species) to act as pollinators; *B. terrestris*, especially, is well-established in alpine areas foraging up to 2500 m (Donovan, 2007). However, due to different foraging preferences and nesting requirements, *B. terrestris* does not appear to compete directly with native solitary bees (Iwasaki et al., 2018).

New Zealand has more introduced plant species than there are native plant species (Wilton and Breitwieser, 2000), and 31 species of naturalized introduced mammals (Parkes and Murphy, 2003). However, relatively few of these have become established in alpine areas, especially away from human activities (Mark and Dickinson, 1997; Mark, 2012). Mice and hares can be more abundant in alpine grassland compared with montane forest, and mice appear to have a significant impact on alpine invertebrates, especially weta (Wilson et al., 2006). Rats are largely restricted to lower altitudes by a combination of food availability and temperature. However, they may be able to invade upslope during mild winters (Christie et al., 2016). Ungulates introduced by European colonists for hunting, particularly Red Deer (*Cervus elaphus*), Chamois (*Rupicapra rupicapra*), and Himalayan Thar (*Hemitragus jemlahicus*), have formed large self-sustaining populations in South Island mountains and can significantly damage vegetation by trampling and heavy browsing (Cruz et al., 2017).

The most serious threat to New Zealand’s alpine ecosystems from introduced plants is posed by the spread of Northern Hemisphere conifers. *Pinus* species introduced for timber were noted to be forming wild populations as early as the late 1800s (Froude, 2011b). Despite this, significant areas of infestation were not recorded until the 1940s, possibly coinciding with changing farming practices (Froude, 2011a). Currently more than 25 introduced conifers have formed self-sustaining populations in the wild (Froude, 2011b) and some species such as *Pinus contorta* have greater frost tolerances than native timberline trees (Wardle, 1985). The ability of these species to withstand the stressors of alpine environments has enabled them to readily invade alpine grassland ecosystems well above natural timberline (Cieraad and McGlone, 2014). In 2007 wilding conifers were estimated to threaten 805,000 ha of eastern South Island, with spread most prevalent in inland montane basins and ranges, including alpine areas (Froude, 2011a). The conversion of these alpine grassland ecosystems into exotic coniferous forests is undoubtedly leading to the loss of native alpine species.

Tourism is New Zealand’s largest industry in terms of foreign exchange earnings and the number of international visitors per annum is expected to exceed the size of the resident population by the year 2024 (Driver, 2018). Popular alpine areas are heavily used for sight-seeing, tramping/hiking and skiing. For example, view points for the highest peak, Aoraki/Mt. Cook, now attract more 1 million visitors per year, putting severe strain on current facilities (Littlewood, 2019). The number of visitors to Franz Joseph

Glacier reached 750,000 over the 2017/2018 season and 130,000 visitors attempted the Tongariro Alpine Crossing in central North Island in the same season (Driver, 2018). The New Zealand ski industry has a target of 2 million skier days by 2020 (Jamieson, 2018), placing considerable pressure on the alpine areas utilized, especially in terms of water consumption for snow making and solid waste disposal (Reiser, 2002).

Changing Climatic Conditions

New Zealand has a distinctly oceanic climate with cool summers and mild winters. This leads to an extended growing season at high altitudes. However, summers are not predictably warm and frosts can occur at any time of the year (McGlone et al., 2010; Lord et al., 2018). Winter snow cover is also not predictable and in low alpine ecosystems soils go through freeze-thaw cycles leading to frost heave and subsequent surface feature sorting such as solifluction terraces, rock nets, and plowing boulders (Mark and Dickinson, 1997; Bliss and Mark, 1974; Grab et al., 2008). Climatic variation between years in New Zealand alpine ecosystems is also affected by the El Niño-Southern Oscillation system of linked changes in sea temperature and atmospheric pressure across central and eastern Pacific. Under El Niño summer conditions the west-east rainfall gradient across the Southern Alps becomes exaggerated, leading to heavier than normal precipitation on western areas and drought in eastern alpine areas. El Niño also increases the frequency of southerly airflows in winter, bringing more snow and colder temperatures to much of New Zealand. La Niña has less impact on New Zealand, but is typically associated with warmer temperatures (NIWA, 2019b). New Zealand alpine invertebrates, like other Southern Hemisphere invertebrates, are commonly freezing-tolerant, able to survive internal ice formation (Sinclair et al., 2003; Sinclair and Chown, 2005). These species can go through freeze-thaw cycles on a daily basis, allowing for winter activity should conditions be favorable (Sinclair, 2001; Ramløv, 1999). Similarly, New Zealand herbaceous alpine plants show higher growing season frost tolerances than equivalent Northern Hemisphere species (Bannister et al., 2005). The lack of a predictably warm growing season is thought to explain why the New Zealand native flora as a whole, and the alpine flora in particular contain very few obligate annual species (Lloyd, 1985).

Climate change scenarios for New Zealand based on IPCC 5th assessment models predict temperature increases of +0.7 to +1.0 °C by 2040 and up to +3.0 °C by 2090. This warming trend is predicted to be greatest at higher elevations, with regional climate models suggesting that maximum daily temperatures in the Southern Alps could rise by more than 4 °C by 2100 (NIWA, 2019a; Hendriks and Hreinsson, 2010). As a result, large decreases in snow cover are predicted at high altitudes and in southern regions of South Island (NIWA, 2019a). The duration and depth of seasonal snow is expected to decrease at all elevations but to be especially marked below 1000 m altitude (Hendriks and Hreinsson, 2010). In line with global trends, the New Zealand land-mass has warmed by 0.9 °C in the last century (Mullan et al., 2008), three of the last 5 years have been among the hottest on record for New Zealand, and a third of the ice volume in the New Zealand alpine has been lost in the last 40 years (NIWA, 2019a). However, between 1983 and 2008, when the vast majority of the world's glaciers were shrinking, at least 58 New Zealand glaciers increased in size, most likely due to regional cooling (Mackintosh et al., 2017). This effect was glacier specific and short-lived, e.g., while Franz Josef glacier on South Island's west coast regained at least half of the mass lost in the first half of the 20th century, the Tasman glacier on the eastern side of Aoraki/Mt. Cook continued to retreat. Since 2011 Franz Josef glacier has retreated by 1.5 km, quite possibly linked to warmer temperatures in the Tasman Sea to the west of New Zealand (Mackintosh et al., 2017), which were 6 °C warmer than average in 2018 (NIWA, 2019a). Despite these trends, New Zealand tree lines do not appear to have responded to warming temperatures as much as predicted, with only modest sapling establishment above adult tree line in monitored plots (Wardle, 2008). However, altitudinal increases in treeline seem to be more rapid in diffuse treelines as opposed to the abrupt treelines dominated by southern beech species, suggesting factors other than temperature are important (Harsch, 2010).

As New Zealand alpine species already show adaptations to unpredictable climatic conditions, it is difficult to assess how climate change per se will affect species distributions. The frost tolerances of snowbank species indicate that although these species normally overwinter under snow, they would be able to tolerate increased exposure to winter conditions (Bannister et al., 2005). In a reciprocal transplant experiment on the Rock and Pillar Range, snowbank turfs moved to areas of reduced snow cover showed slow changes in species composition even after 7 years, but the fruticose lichen *Thamnolia vermicularis* showed rapid colonization of newly available snow free areas (Lord et al., 2018). This study concluded that drought during the growing season may be more important to species survival than reduced seasonal snow. The impacts of upward-migrating woody natives and pest species may be of greatest concern for New Zealand alpine ecosystems under a changing climate (McGlone et al., 2010). Introduced small mammals that show intermittent use of alpine areas could have a greater impact under warmer climatic conditions (Christie et al., 2016). Mice in particular, by consuming large numbers of invertebrates and seeds, may limit the ability of native species to migrate successfully with their climatic niches. Assuming the position of treeline is temperature dependent, and given an latitudinal lapse rate of 0.6 °C/100 m, a 3 °C warming scenario could raise New Zealand treelines by 500 m, reducing the area available for alpine plants and resulting in the loss of c. 80% of current alpine "islands" (Halloy and Mark, 2003). As only 0.03% of the total area above treeline is higher than the highest recorded vascular plants, species displaced by upward-migrating woody species would have limited areas in which to expand (Halloy and Mark, 2003). Two alpine summit sites in South Island have been established to measure climate changes and altitudinal migration of species (Mark et al., 2006) as part of the Global Observation Research Initiative in Alpine Environments (GLORIA; Grabherr et al., 2000), and have been regularly surveyed since 2001 (Mt Burns) and 2004 (Mt Pisa). However, it is by no means clear that simple changes in altitudinal range will be observed, or even should be expected, for New Zealand alpine species as has been reported elsewhere (Grabherr et al., 2010), given the topographic and climatic variability of the New Zealand alpine environment; minimal response or counter-intuitive outcomes are possible (McGlone et al., 2010).

Conservation Strategies

New Zealand has the highest proportion in the OECD (Organization for Economic Cooperation and Development) of land area protected for conservation purposes and almost 98% of the land area above permanent snowline and 94% of alpine areas in the Southern Alps have legal protection for conservation (Anon, 2010). However, c. 18% of mountain areas with indigenous plant cover in central and southern North Island, Taranaki and north-eastern South Island, and more than 60% of mountain and hill country areas with indigenous plant cover in south-eastern South Island, still lack legal protection (Anon, 2010). In the last 20 years the amount of alpine land legally protected for conservation purposes has increased significantly as an outcome of High Country Tenure Review. This voluntary government-run process gives pastoral lessees the opportunity to purchase some of their leasehold land, often the lower altitude portions, in exchange for relinquishing rights to other, often higher altitude, parts of their lease, and has led to the formation of high country conservation areas, and improved public access and recreation in South Island alpine areas.

The New Zealand Department of Conservation (DoC) is the government entity responsible for managing the national conservation estate. Activities not only include pest and weed control but also rare species management. The New Zealand Threat Classification System (Townsend et al., 2008) determines the risk of extinction of species and changes in status over time, allowing for species to be prioritized for intervention. Many alpine species are highly range-restricted so feature on threatened species lists, for example 16 of the more than 40 *Myosotis* species in New Zealand are considered threatened due to very small ranges (Meudt et al., 2015). However, because the alpine environment is well represented in the conservation estate, management of alpine species is of less concern than lower altitude species threatened by habitat loss or introduced species. Even so, despite legal protection, a number of alpine species remain on threatened species lists and have continued to decline. For example the iconic alpine parrot, *Nestor notabilis*, kea, was reassessed in 2016 as Nationally Endangered because populations number only 1000–5000 mature individuals, with an ongoing predicted decline of 50–70% over 10 years or three generations (Robertson et al., 2017).

Conclusions

The alpine ecosystems of New Zealand are the most significant in the Southern Hemisphere apart from South America. Due to New Zealand's geographic isolation and geological history, recent rapid speciation has produced a high diversity of endemic taxa, many of which are yet to be described. While global climate change may not have as much impact on alpine species in New Zealand as elsewhere, the combined threats posed by invasion plants and animals, and anthropogenic pressures are significant. Thus the future security of New Zealand's alpine ecosystems depends largely on government commitment to large scale control of high impact pests such as introduced conifers and browsing mammals, as well as ensuring that the regulations that control alpine activities prioritize biological conservation over economic development.

Abstract

The evidence of global temperature rise is now widely accepted. On average the global temperature rose by 0.74 °C over the last hundred years (1906–2005), with more than half of this rise, i.e., 0.44 °C reportedly occurred in the last 25 years. Subsequently, the number of extreme precipitation events—like heavy rainfall and severe storms—appears to have increased. According to the fourth assessment report of the Intergovernmental Panel on Climate Change (IPCC, 2007) “most of the observed increase in globally averaged temperatures since the mid 20th century is very likely due to the observed increase in anthropogenic greenhouse gas concentrations.” Such changes in climate have already started affecting biological systems worldwide. Significant upward shift of plant species have already been reported from many parts of the globe due to warming. Several studies have detected effects of climate change on species distribution, the storage of carbon in plants and soils, and the timing of life history events of animals and plants. The change in climate will also affect the livelihoods and food security of the regional inhabitants who depend on the natural resources of high mountains. This article presents an overview of impacts of climate change in Himalayan mountains on agriculture and forest ecosystems based on literature review and some anecdotal evidence.

Introduction: Climate Change in the Himalaya

In the next few decades, the mountains of the world are predicted to continue warming at an alarming rate. During the last few decades, the Himalayas have experienced approximately two to three times greater atmospheric temperature warming than the global average (Xu et al., 2009). Temperature trends in most Himalayan regions substantially exceed the global mean trend of 0.85 °C (between 1880 and 2012), with winter season temperature trends being generally higher than those of other seasons (Schickhoff et al., 2015). The greatest average increase, 0.07 °C/year is observed in winter, whereas the least increase, 0.03 °C/year in summer (Shrestha et al., 2012); and the warming rate increases with altitude, peaking between 4800 and 6200 m altitudes (Singh et al., 2011). The IPCC predicts that average annual mean temperature over the Asian land mass, including the Himalayas, will increase by about 3 °C by the 2050s and about 5 °C by the 2080s (IPCC, 2007), and average annual precipitation will increase by 10–30% by the 2080s (IPCC, 2007). Satellite imagery suggests almost 67% of the glaciers in the Himalaya have retreated. For example, in Nepal (Central Himalaya) glacial margins are retreating by as much as 10 m/year (Ageta and Kadota, 1992). It has been stated that in the face of climate change (CC) most ecosystems and landscapes will be impacted through changes in species composition, productivity and biodiversity. Thus, the magnitude of potential response of the climate-sensitive Himalayan region needs to be better understood. As glacier margins recede, and snowlines move upwards, river flow rates are likely to change. Furthermore, an alteration in water flow regime may lead to a plethora of social issues, endanger biological communities, impact forestry and agriculture-based livelihoods and affect the overall well-being of the people.

Dimri and Dash (2012) reported that the Western Himalayan region shows a warming trend of 0.2–0.4 °C/decade. Consistent warming signature over IHR, more than the global average, was reported by the north-western Himalaya by Bhutiyani et al. (2007) for the last century. Dash et al. (2012) reported that warming over north-east India was around 0.2 °C/decade during 1971–2005. Similarly, warming rate of Nepal Central Himalaya during 1977–2002 was also reported to be 0.6 °C/decade by Shrestha and Aryal (2011). Moreover, statistically significant projected warming rate of 0.23–0.52 °C/decade was reported by Dimri et al. (2018) for minimum and maximum air temperatures under RCP 4.5 and 8.5 by 2099. Recently, Singh (2019), based on 32 yrs. observed data between 1980 and 2012 for a central Himalayan site Mukteshwar (an IMD station in Uttarakhand), showed that annual average maximum and minimum air temperature (observed at 2 m height) were significantly (P -value < .05) increasing (0.01 and 0.02 °C/decade). These studies indicate that the Himalayan region is probably warming at rates higher than the global average.

In the Indian Himalayan Region (IHR), the rainfall processes of both summer monsoon seasons and winter western disturbances are significantly modulated by the complex terrains through terrain-induced changes in the convection process, vapor flux, cloud water content and wind distribution. Subsequently, significant rainfall variability due to complex terrain and increasing temperature may lead to excessive landslides, induced disasters, and increased flooding of rivers and rivulets. Therefore, many reports have been published on the long-term changes in rainfall over different stations of IHR with various degrees of change, for

example positive trends (i.e., increasing seasonal and/annual mean of rainfall) in the rainfall pattern for some local regions, as reported by Sharma et al. (2000) for Kosi basin in Nepal and by Kumar et al. (2005) for Himachal Pradesh, India. Similarly, negative rainfall trends are reported by Singh and Sen-Roy (2002) for Beas basin and Kumar and Jain (2010) for Qazigund and Kukarnag of Kashmir. No significant changes in rainfall were reported by Archer and Fowler (2004) for the upper Indus basin, for the Jhelum river basin of Pakistan (Khan, 2001), and for the Almora and Nainital towns of Uttarakhand state, India (Joshi et al., 2013). Kumar et al. (2008) reported that the annual rainfall has decreased by 3.91 mm in 11 years. between 1991 and 2001 in the Alaknanda valley of Garhwal Himalaya, and the mean annual temperature has increased by 0.15 °C, in 40 years. between 1960 and 2000. A spatial analysis of the summer monsoon rainfall trend over IHR by Mukherjee et al. (2014) further reveals that both monsoon *strong* and *weak* phases are decreasing for the entire Himalayan region with seasonal average rainfall trend is decreasing for the eastern Himalayan states. However, a dominant cycle of ~ 2.7 years of high frequency of extreme rainfall events over the IHR was reported by Mukherjee et al. (2014). Moreover, it was reported that projected rainfall amount is expected to increase by 0.75 mm/day over the northwest Himalaya, whereas the flood plain of Assam is expected to receive less rainfall during 2020–70 (Mukherjee et al., 2017).

Climate change has emerged as a major issue across the globe. The mountain regions, including the Himalaya, are particularly vulnerable to CC on two main counts: (i) warming trends are higher in the region, and (ii) the impacts are magnified by the sharp change in altitude over small distances. However, we still lack sufficient climatological data for much of the Himalayan region. In particular, good data are needed for the Himalayan region to assess the current situation of CC impacts, and to make reliable predictions that can be used as a basis for planning. In spite of global attention, CC research is still in its infancy in the Himalayan mountains. As such there is a paucity of long-term climate data in the region and the available data has been collected without any uniform instrumentation and methodology, hence, the magnitude of observed data and data quality is uncertain. Limited studies are available which may demonstrate the impact of CC on mountain ecosystems.

Impacts on Food Production Systems and Livelihoods

Agriculture is the mainstay of mountain people in the western Himalayan region. Mountain agriculture is mostly rain-fed (~85%), and dependent upon biomass energy (fodder for livestock, manuring leaves, fuelwood, wood for agricultural implements, wild edibles etc.) derived from the surrounding forests. The small holdings (size >1 ha of majority of people) distributed over rugged terrain have low agricultural productivity (~1 t/ha), yet it is a rich repository of agro-biodiversity and the region is resilient to crop diseases. For example, in Uttarakhand, over 40 different crops and hundreds of cultivars comprising cereals, millets, pseudo-cereals, pulses and tuber crops are cultivated (Maikhuri et al., 2001). Mixed cropping of 12 crops (Baranaja) is another best example of rich agri-diversity of the region. These crops are adapted to the local environmental conditions and withstand the environmental risks and other natural hazards and thus have contributed to the food and nutritional security of the hill farmers for many generations. However, in recent decades the area planted with traditional crops has drastically decreased (>60%), and many of the crop species are on the brink of extinction, such as *Panicum miliaceum*, *Glycine* spp., *Setaria italica*, *Hibiscus sabdarffia*, *Vigna* spp., and *Perilla frutescens*, to name a few (Negi and Joshi, 1996). The irrigation systems (locally called as guls), have been severely damaged with the rainfall becoming erratic and springs are drying. Similarly, a comparison of climate data reveals the negative impact of CC on fruit yields, as reported in the Kullu valley (Himachal Pradesh). This is apparently the result of decreased rainfall by about 7 cm, decreased snowfall about 12 cm, and an increase in the mean minimum and maximum temperatures by 0.25–1 °C (Vishvakarma et al., 2003). Also, it has been reported that apple cultivation has shifted to higher altitudes and that apple yields from orchards at lower altitudes have declined due to inadequate and delayed snow fall. The temperature at lower altitudes is also rising due to CC. Alterations in the floral diversity due to land use and land cover change and extinction of local cultivars has also negatively affected the population of pollinators (native bees) in the region resulting in inadequate pollination and decline in apple productivity (Partap and Partap, 2003). The farmers are now compelled to rent colonies of honey bees for pollinating the apple orchards, and devise short-term solutions until the “polliniser” trees in their orchards begin flowering.

Some of the documented impacts on mountain food production systems linked with CC in the Himalayan region are (Negi et al., 2012): (i) reduced availability of water for irrigation; (ii) extreme drought events and shifts in the rainfall regime, resulting in failure of crop germination and fruit set; (iii) invasion of weeds (e.g., *Lantana*, *Parthenium*, *Eupatorium*) in the croplands; (iv) increased frequency of insect-pest attacks; and (v) decline in crop yield. These factors have led to loss in agri-diversity and change in crops and cropping patterns in the Western Himalayan region, leading to abandonment of crop fields and out-migration of people.

Impacts on Biodiversity and Forest Ecosystems

Among global mountains, the Himalayan region is most prominent on account of the height of its mountains and the length of the range. The Himalayas represent one of the 36 “Global Biodiversity Hotspots” (https://en.wikipedia.org/wiki/Biodiversity_hotspot). The richness of endemic species with restricted distribution and life support values (goods and services) of these hotspots is highly vulnerable under the changing climate scenarios (Palni and Rawal, 2013). Vegetation patterns (distribution, structure and ecology of forests) across the globe are controlled mainly by climate. Several climate-vegetation studies have shown that certain climatic

regimes are associated with particular plant communities. The Fourth Assessment Report of IPCC (2001) concluded that forest ecosystems could be seriously impacted by future CC. Even with global warming of 1–2 °C, much less than the most recent projections of warming during this century (IPCC, 2001), most ecosystems will be impacted through changes in species composition, productivity and biodiversity (Leemans and Eickhout, 2004). It has been demonstrated that upward movement of plants will take place in a warming world (Kelly and Goulden, 2008). In a recent study the expansion and upward movement of *Rhododendron campanulatum* along an altitudinal transect (3511–3665 m asl) running from the upper forest limit to the treeline and beyond in Uttarakhand was estimated at 1.4 m/year (Singh et al., 2018) due to rising temperatures (0.11 °C/year in the past two decades) (Table 1). Studies in the western Himalayas have recorded an upward shift of treeline species of 19 and 14 m over 10 years on south- and north-facing slopes, respectively (Dubey et al., 2003). Due to increase in temperatures, change in vegetation, rapid deforestation and scarcity of drinking water, habitat destruction and ecological corridor fragmentation may lead to extinction of wild flora and fauna. In some high altitude regions, the biodiversity is being lost or endangered because of land degradation and the over- use of resources. For instance, in 1995, about 10% of the known species in the Himalayas were listed as threatened.

The impact of atmospheric warming is clearly observed in the changing phenology of plant life in the region, in particular, the timing of the onset of growth of plants, particularly flowering in this region. Phenological studies in Kumaun Himalayan forests (Sal, Pine, and Oak forests) has revealed the mean date of leafing and flowering has advanced by 1–2 weeks within a period of 30 years (1985–2015) due to the increase in temperature (0.005 °C/year) and decline in rainfall (3.3 mm/year) over the years (Singh and Negi, 2016). In these species a rise in temperature and water stress may advance seed maturation, which might breakdown the synchrony between monsoon rains and seed germination, thus reducing forest regeneration, and the species diversity of forests. The flowering and fruiting at the wrong time, in advance or after the appropriate season, may lead to failure in finding pollinators, failure to match demands of growing offspring with temporal peaks in food resources, or failure by a pollinator to find pollen and nectar, or of a flower to be pollinated. Climatologists believe that even with global warming of 1–2 °C, much less than the most recent projections of warming during this century, most ecosystems and landscapes will be impacted through changes in species composition, productivity and biodiversity (Leemans and Eickhout, 2004). It is expected that with the CC, scenario of the forests, both in terms of structure and functioning, is likely to change substantially. In the case of many dominant forest species of the region, such as sal (*Shorea robusta*), tilonj oak (*Quercus floribunda*) and kharsu oak (*Q. semecarpifolia*) seed maturation and seed germination have traditionally coincided with monsoon rainfall. In wet conditions these species show vivipary (germination of seeds while they are still on trees). A rise in temperature and water stress may advance seed maturation, which might result in the breakdown of synchrony between monsoon rains and seed germination of these species (Singh, 2014).

In the western Himalayan mountains, early flowering in several members of Rosaceae (e.g., *Pyrus*, *Prunus* spp.) and *Rhododendrons* has often been linked with global warming. Earlier onset of flowering in *Rhododendron* about two weeks as compared to the past has been reported in Kumaun Himalaya. A Generalized Additive Model (GAM) using real-time field observations (2009–11) and herbarium records (1893–2003, Hooker 1949) predicted 88–97 days early flowering over the last 100 years in *Rhododendron arboreum* due to a rise in annual mean maximum temperature in Western Himalaya (Gaira et al., 2014). Ranjitkar et al. (2014) has reported that tree *Rhododendron* might expand its distributional range in response to global warming under the recent trend of rising winter-spring temperature (Xu et al., 2009). Telwala et al. (2014) reported range shifts of 87% of the 124 endemic species as a consequence of winter warming in the alpine zone of the Sikkim Himalaya, using historical climatic and taxonomic data from 1849 to 50 and 2007–10. Similarly, significantly ($P < .01$) earlier flowering was recorded for 11 alpine/sub-alpine and 12 temperate high-value medicinal herbs, in response to increasing winter temperature. Alpine species confined to the tops of low-lying mountains face the risk of extinction as their habitats are likely to be taken over by the forests. Literature reports indicate that climatic conditions are more useful “predictors” than the calendar dates. For example, photosynthesis is an important parameter that is affected by changing temperature, CO₂ and light conditions. However, many of these studies suffer from the lack of long-term meteorological data to establish a clear-cut relationship with CC and there is a pressing need for observational climatic data in the region.

Forests are also the source of NTFPs (including medicinal plants). The oak forests (*Quercus* spp.), native of the cool temperate climate of the region, are the storehouse of biodiversity, non-timber forest products (NTFPs), and a variety of medicinal plants. For example, *Morchella esculenta* (an edible fungi), found in the oak-conifer forests of this region, is collected by the local people. On average, each household collects about 1.5 kg dry wt. every year which is sold for 5000 rupees, or \$72 US per kg. Another

example is *Myrica esculenta* fruits. These are collected by local people from the forests that are sold in the nearby markets. The spread of invasive, exotic and alien spp. (e.g., *Lantana*, *Eupatorium*, and *Parthenium* spp.) in the natural forests of this region has also been linked with CC. These have a competitive impact on the native flora. Increased incidences of forest fire are another prominent change that is linked with CC. The frequency, size, intensity, seasonality, and type of fires depend on weather and climate in addition to forest structure and composition. A comparison of air temperatures during the fire season for the 2 years 1994 (no fire event) and 1995 (large fire events) in Binsar Wildlife Sanctuary, Western Himalaya showed that in 1995 the air temperature was higher (Sharma and Rikhari, 1997). It is expected that with the increase in drought cycles and concomitant increase in forest fires, the NTFPs derived from oak (*Quercus* spp.) forests will decline. Apart from the direct benefits accrued from these forests the ecosystem services generated by these forests would also alter. Singh (2007) has estimated the carbon stocks of the forests of Uttarakhand Himalaya at 264 million tons. Inevitably, any change in the forest (distribution, density and species composition) under CC would immensely influence economies like forestry, agriculture, livestock husbandry, NTFPs, medicinal plants and many others. The ability of species to respond to climate change will depend on their being able to “track” shifting climatic zones and colonize new territory or to adapt their physiology and seasonal behavior to changing conditions.

Impact of Climate Change on People

The impacts of CC on the socio-economic conditions of people living in the Himalaya can be observed in agriculture, livestock, forestry, tourism, fishery, as well as human health (Sharma et al., 2009). However, specific knowledge and data on the impacts of CC on human well-being in the Himalaya is limited. Regional inhabitants depend heavily on forest resources, therefore the consequences of biodiversity loss from CC are likely to be the worst in case of the poor and marginalized people who depend almost exclusively on natural resources. This region is characterized by poverty, poor infrastructure (roads, electricity, water supply, education and health care services, communication, and irrigation), and other indicators of underdevelopment, making the Himalayan inhabitants more vulnerable to CC because their capacity to adapt is quite low. Signatures of the impacts of CC on human health are now becoming apparent through changes in the ranges of disease vectors (e.g., mosquitoes), water-borne pathogens, water quality, air quality, food availability and quality (McMichael et al., 2003) and malnutrition from crop failures (Patz et al., 2005). With a rise in surface temperature and changes in rainfall patterns, the distribution of vector mosquito species may change (Patz and Martens, 1996). Malaria mosquitoes have recently been observed at high altitudes in the region (Eriksson et al., 2008). Huge quantities of municipal waste produced in the mountain towns is further compounding the problem of emission, sanitation and associated health hazards. Another health hazard is posed due to burning of pine forests that give rise to smoke containing sulfur dioxide, benzopyrene, carbon monoxide, nitrogen oxides, polycyclic hydrocarbons and albeitic acid. These gases alone or along-with carbon could be the responsible factors for lung injury with fibrosis (Rison et al., 2000). Aerosols have been shown to contribute to global warming. Based on per unit AOD increase at Mohal-Kullu (Himachal Pradesh, Western Himalaya), temperature rise due to radiative forcing from aerosols in the atmosphere was calculated as high as 0.95 °C per day during summer (April–July) and as low as 0.51 °C per day during winter (December, January–March) (Guleria et al., 2001). Climate change will increase the incidence of diarrheal diseases from deteriorating water quality, as well as increases in infectious diseases and the frequency of cardio-respiratory diseases from the build-up of high concentrations of air pollutants such as nitrogen dioxide (NO₂), lower tropospheric and ground-level ozone, and air-borne particles in large urban areas.

Issues for Future Action

In the current context of changing climatic regime, it is imperative that a proper assessment of long-term changes in the climate parameters be made on a variety of spatio-temporal scales across the different landscapes in the Himalayan region so that sector-wise targeted adaptation and mitigation practices and policies can be framed. However, such detailed assessment of long-term changes in regional climate parameters is greatly impeded by the lack of sufficient data. The IHR, in addition to Nepal and Bhutan contain significant numbers of unique, climate sensitive bio-diversity hotspots and socio-cultural diversity. However, as discussed above, this region lacks sufficient climate data. This lack of data causes the Himalayan region to be under reported in most climate change studies (Singh et al., 2011; IPCC-AR5, 2014). However, scientific interest in quantifying long-term changes in climatological parameters of the IHR, particularly rainfall and surface air temperature, has grown in the last decade. Also, the lack of systematic information on the impact of CC on Himalayan biological systems is widely recognized. Likewise, the need for the development of a Himalayan database among ecologists at the global level has also been highlighted. Therefore, strong initiatives are required not only to utilize but to further strengthen existing databases on Himalayan ecosystems so as to enhance our ecological understanding of CC impacts. This is the only way to properly address issues of conservation and management of Himalayan ecosystems at the local and regional level.

Abstract

The alpine biome is the life zone above the climatic treeline in mountains. It is the only biome that has a global distribution, with its elevation varying with latitude. Being naturally treeless by definition, its vegetation is composed of small stature plants belonging to the life form graminoids (grasses, sedges, and rushes), herbs, dwarf shrubs and cushion plants covering c. 3.55 Million km² or 21.5% of the global mountain area of 16.5 Million km². Driven by the combination of small, compact plant stature and topography effects (exposure, direction to the sun and shelter) the actual climate experienced by these plants and the animals and microbes associated with them is much warmer (heated by the sun) than one would expect from weather station data. This physical manipulation of an otherwise harsh climate explains much of the physiology observed in alpine plant taxa. Because nights are cool, and—at extratropical latitudes—as the growing season gets increasingly short the productivity of alpine ecosystems is limited by the duration of favorable daytime periods and the slow nutrient cycle. Alpine plants are well adapted to the life conditions they experience, and counter wide spread belief, are not particularly stressed. Because topographic diversity provides escapes from unpleasant habitat conditions over very short distances, the alpine biome and its biodiversity are not particularly vulnerable to climatic change, but rather represent refugia that deserve protection.

The Alpine Biome

In the scientific literature the term alpine refers to the land above the low temperature limit of tree growth, the natural high elevation treeline (see treeline Chapters). Hence, by definition, the alpine life zone is treeless. When trees had been cut or burnt locally, or are absent for other reasons (avalanches, lack of soil, etc.), the treeline is not visible in the landscape, with the montane forest replaced by a low stature vegetation (e.g., meadows, hay fields). This sometimes “alpine looking” substitute vegetation does not belong to that alpine life zone but belongs to the montane life zone. Note the difference between the general term mountain for elevated and rugged land (see below), and the term montane that refers to the upper part of mountains that could be forested but may not bear any trees for disturbance reasons or lack of soil or water. These distinctions are important because they place that alpine life zone in a specific elevational belt that is characterized by climate and not by elevation. In other words, the alpine life zone is confined to a high elevation temperature regime that does not support tree growth. Note, in English, “elevation” applies to elevated land, while “altitude” refers to the height above ground in the free atmosphere; [McVicar and Körner, 2013](#)).

Defined that way, the alpine life zone occurs globally where mountains are sufficiently high ([Fig. 1](#)). The alpine biome is thus the only biome that has a global distribution across all continents (except Antarctica) and it occurs across all latitudes—though at varying elevations. Its common environmental determinants are a lower limit set by the climatic treeline (see above) and the ultimate low temperature limit for plant life, the upper range limit of the alpine biome. That uppermost, often very fragmented part of the alpine world is often addressed as “nival,” because it occurs above the lower limit of potentially permanent snow fields or glaciers. Readers are invited to “visit” the alpine biome across the globe at www.alpandino.org, an open access electronic course that introduces life and life conditions in alpine ecosystems around the world.

The common biological features of the alpine biome are plants of small (commonly less than 0.5 m) size that form shrub land near treeline, followed upslope by graminoid communities and open, fragmented alpine (and nival) vegetation with isolated plants at highest elevations. The term graminoid is employed here because it includes similar life forms that belong to several plant families such as grasses (Poaceae), sedges (Cyperaceae), and rushes (Juncaceae). Although these plants may look like grasses to a lay person, they belong to very different groups of plant species (see life forms below). The commonly small size (stature) of alpine plants has substantial beneficial effects on the actual climate experienced by these plants and the animals and microbes associated with them (the so-called microclimate, see below) and it has implications for sensitivity to disturbance (e.g., grazing, fire, and wind).

How large is the global fraction of land that belongs to the alpine biome? To answer this question, we must first define the term “mountain,” with the alpine biome a subunit of the global mountain area. Mountains are not defined by elevation but by the ruggedness of the landscape. The plains of the short grass prairie at 2000 m elevation are not mountains, but steep coastal ranges

Fig. 1 The alpine biome. Examples from different latitudes (from top left to bottom right): (1) arctic-alpine (Sweden, 69°N, 1100 m), (2) temperate-alpine and nival (Swiss Alps, Rhone glacier, 47°N, 2200–3500 m), (3) temperate-alpine grassland (Austrian Alps, Hohe Tauern, 47°N, 2300 m), (4) temperate-alpine heathland (Chile, Cerro Castillo, 46°S, 1300 m), (5) semiarid tropical-alpine (Bolivia, Sajama, 19°S, 4800 m), (6) humid tropical-alpine (Bolivia, Sajama, 19°S, 4300 m).

with summits only a few hundred meters above sea level are clearly mountains. A 200 m span of elevation over a distance of c. 2.5 km comes very close to what most people consider a mountain. Using that threshold in a 30'' gridded global digital elevation model, the resulting global mountain area is 16.5 million km², 78.5% of which belong to the montane belt (i.e., potentially forested; Körner et al., 2011).

When the alpine fraction is defined as land above the treeline isotherm (at least 94 days with a seasonal temperature of 6.4°C and the season defined as any day with a daily mean temperature >0.9°C (the outcome of a global statistical analysis by Paulsen and Körner, 2014), the total alpine land area amounts to 3.55 million km², which represents 21.5% of the global mountain area (including a 3.2% nival fraction) or 2.6% of all land area outside Antarctica. The geo-statistics shown in Table 1 are restricted to discrete mountains one can identify on a map (83.3% of all rugged terrain). Done this way, the global alpine area is almost the same (3.3 million km², 24% of all mountain area) because the remaining rugged terrain has hardly any alpine land). The alpine biome is not distributed equally on all continents, but is largely confined to Eurasia and the Americas, with only tiny alpine land areas in Africa, Australia and Oceania (Table 1). These statistics do not include the treeless Arctic lowlands, also covered by short stature plant communities that are often subsumed under the term tundra or Arctic semi-desert, both lacking the characteristic features of the alpine landscape, its ruggedness and thus, high habitat diversity. Not surprisingly these arctic ecosystems are much poorer in plant species. While the total alpine flora may comprise about 10,000 species of flowering plants (Körner, 1995), the entirety of these lowland Arctic systems hosts about one seventh as many flowering plant species (Chapin and Körner, 1994). While steepness of terrain is a typical feature of alpine ecosystems, many Arctic systems cover flat lands and hill country, often dominated by

Table 1 The global alpine biome: land cover statistics (Körner et al., 2011, 2017)

Region	Nival belt (km ²)	Upper alpine (km ²)	Lower alpine (km ²)	Total alpine (km ²) (%Mt) ^a	Total mountain (km ²) (% of global) ^b
Africa	43	85	963	1091 (1.5)	706,257 (5.1)
Asia	196,031	420,559	1,356,970	1,973,560 (26.0)	7,600,456 (55.2)
Australia	0	0	1010	1010 (1.4)	74,747 (0.5)
Europe	58,401	34,845	63,721	156,967 (20.0)	784,679 (5.7)

Total	460,747	701,216	2,146,652	3,308,615 (24.0)	13,759,859 (100)

^aAlpine land area fraction (in %) of the total mountain area in the region.

^bContribution of the regional (continental) mountain area to the global mountain area. Note the 13.76 million km² of mountain terrain includes only the area of discrete ca. 1060 mountain ranges with a name (83.4% of all mountain terrain, mountain polygons, Körner et al., 2017). An additional c. 2.7 million km² of rugged terrain that falls in the mountain category is distributed diffusely across the globe and commonly has no alpine belt (many, very small mountains). With this terrain added, the global mountain area rises to c. 16.5 million km² (100%) outside Antarctica (Körner et al., 2011).

peatland (mires, fens), which are rare in mountains. Hence the term “tundra” is best not applied to the alpine biome (Billings, 1988). However, subarctic mountains do also have alpine ecosystem (arctic-alpine ecosystems; Fig. 1).

Because of the wide latitudinal range across which alpine ecosystems occur, their elevational position varies greatly. While alpine life conditions can be found a few hundred meters above sea level in the subarctic, similarly cool conditions can be found at 4000–5000 m elevation near the equator, although with a longer (often year-round) growing season. The highest location of flowering plants is found in the Himalayas at ca. 6300 m elevation (Körner, 2003), but this is not the coldest place on earth with flowering plants (angiosperms), which was actually discovered in the temperate zone at 4505 m elevation in the Swiss Alps (Körner, 2011). So elevation as such is not a suitable factor to describe the alpine biome. What matters is the climate that is associated with elevation.

Life Forms of Plants That Shape the Alpine Ecosystem

A life form is a category of plant architecture, irrespective of the taxonomic, phylogenetic association. The assembly of plant life forms shapes the nature of biomes. As explained above, the alpine biome is characterized by the absence of tree life forms, but also lacks tall shrubs and lianas, all typically stretching high into the air, and thus forced to “take over” ambient air temperature. Not so the typical alpine life forms described below (Fig. 2).

Alpine herbs are commonly those with leaves forming a rosette attached to the ground, represent the most diverse alpine life form. They commonly fill the space between graminoid tussocks. Most of these herbs spread by below ground rhizomes or runners, hence form clonal systems as well. Alpine herbs also belong to the highest elevation taxa, reaching far into the nival belt. However, most alpine biomes also host some tall herb taxa, which are mostly confined to sheltered, nutrient-rich locations.

The graminoid life form (see above) covers the core of the alpine landscape in most parts of the world (often addressed as alpine grassland or heathland). Most commonly, these graminoids form so-called tussocks, that is, tufts of tillers confined to a common (clonal) root stock. The buds for the next growing season are below ground (1–3 cm), and thus, can hardly become damaged by trampling, grazing, fire or freezing.

Dwarf shrubs are commonly not taller than 50 cm, with taller individuals confined to lower elevation when the montane forest is absent. At higher elevation, these woody species can become prostrate and form dense carpets, closely attached to the ground. The buds for next season's growth are above ground. Layering stems produce adventitious roots permitting these plants to form large clonal systems (vegetative spreading).

Cushion plants represent the most compact life form. These plants occupy raw or eroded terrain, and they trap the annual plant debris (leaf litter) inside often dome shaped canopies. Thus, the benefit of this life form is a closed nutrient cycle at the price of slow growth, and thus, low competitiveness.

In addition, alpine biomes are rich in so-called cryptogams, that is, mosses (bryophytes) and lichens (a symbiosis of fungi and algae). Many of these tolerate periodic desiccation, and thus can grow without roots, even on bare rock. A special feature are so-called cryptogram crusts that may cover large areas of otherwise bare land and prevent substrate erosion. They pioneer soil formation, for instance, in glacier forefields (Table 1).

Fig. 2 Typical life forms of plants in the alpine biome (from top left to bottom right). Rosette forming herbs: (1) *Alstroemeria spatulata*, Portillo, 2850 m, Chile; (2) *Gentiana algida* and *Pedicularis* sp., Tibet 4600 m, China. Graminoids: (3) *Carex curvula*, Swiss Alps, 2500 m; (4) *Kobresia* (syn. *Carex*) *pygmaea*, Tibet 4600 m. Cushion plants: (5) *Dracophyllum muscoides*, Old Man range, 1650 m, New Zealand; (6) *Saxifraga biflora*, Swiss Alps, 2500 m. Dwarf shrubs: (7) prostrate *Loiseleuria* (syn. *Kalmia*) *procumbens*, Swiss Alps, 2450 m; (8) *Rhododendron*-shrub at the low edge of the alpine belt at treeline, Yunnan, 4300 m, China.

Alpine Life Conditions

Given that the alpine biome is confined to certain climatic conditions (not suitable for tree growth) rather than elevation as such, the question arises: What are the common factors that separate the climate of the alpine biome from biomes at lower elevation. There are actually only a few factors that change with elevation in a common manner, globally. These include the reduction of atmospheric pressure (and the partial pressures of oxygen and CO₂) by about 10% per km of altitude and the associated drop in atmospheric temperature between 0.5 and 0.6 K per 100 m (Kelvin is the preferred unit to refer to temperature differences to avoid confusion with temperature in °C; [McVicar and Körner, 2013](#)). Also clear sky solar radiation and the fraction of UV-radiation increase with elevation, but not the dose of solar radiation as such, because cloudiness often increases with elevation. Neither wind speed nor precipitation change in a consistent way with altitude across the world's mountains ([Körner, 2003](#)). There are alpine deserts above the convective cloud layer in some (tropical and subtropical) regions, and mountains belong to the least windy parts of the globe, except for exposed summits and ridges.

Alpinists often find the alpine environment harsh. However, this is a very human perspective. First, a mountaineer experiences atmospheric conditions between 1 and 1.8 m above the ground, and second, evolution did not select humans for alpine life. The environment experienced by alpine organisms is very different from that experienced by an alpinist or that a weather station might report. Hence, it is not appropriate to apply weather station data to explain alpine life conditions (Körner and Hiltbrunner, 2018).

Aerodynamics are key to understanding alpine plant life and the functioning of the alpine biome. Because alpine plants are “small by design” (genotypically), they would not grow much taller, even if brought to lower elevations. They are evolutionary dwarfs. As such, they can engineer their microenvironment in a way that is much warmer than that recorded by a weather station. Roughly half of the solar radiation belongs to the long wave spectrum (warmth) and even part of the short wave spectrum (light) becomes converted to warmth once absorbed by a structure. So any sun-exposed surface will warm up. This heat is dissipated to the air surrounding this structure. In tall structures (e.g., a tree) that heat would be blown away by wind. In dense, low stature plant communities, this heat exchange is delayed. This explains why alpine plants operate at surprisingly warm temperatures during the day (see discussion below). In fact, it has been shown that their photosynthetic metabolism is adjusted to the same high temperatures as experienced by plants of low elevation. Under bright weather conditions during the growing season, compact alpine plants may warm up to 30°C. Inflorescences may also heat up substantially above air temperature (Fig. 3).

Yet, without solar radiation, that is during the night and during the cold season under snow (winter) in seasonal climates (outside the tropics), alpine plants do experience cold conditions. Snow cover plays a key role in controlling life conditions in winter. Without snow protection, alpine plants may experience (and have to tolerate) temperatures down to −30°C, while under an insulating snowpack, temperatures rarely drop below 0°C. Not surprisingly, snow distribution is a key driver of plant species distribution (Spasojevic et al., 2013). Snow distribution, in addition to wind and solar radiation during the growing season, strongly interacts with topography. Therefore alpine landscapes are characterized by a mosaic of rather contrasting life conditions over short distances.

A single alpine slope may provide locations with seasonal mean temperatures for growing plant tissues at 2500 m elevation that differ by 10 K, thus they differ as much as air temperatures differ over 1700 m of elevation (if a decline of temperature by 0.6 degree per 100 m of elevation is assumed; Scherrer and Körner, 2009). For this reason, alpine landscapes are relatively safe havens for vegetation when the climate changes, because organisms can find suitable habitats over a few meters’ distance (Scherrer and Körner, 2011).

Alpine soils are often poor in nutrients, with a high fraction of nutrients trapped in soil organic matter, a nutrient fraction not available to plants. Alpine soils are often peaty or highly leached and quite acidic. For that reason highly specialized mycorrhizae symbiosis is essential, and these fungi are present even at the highest places where plants occur (Oehl and Körner, 2014). These fungi are essential to make soil nutrients available to alpine plants (Theodose and Bowman, 1997). In regions with a short growing season, this general shortage of soil nutrients is somewhat mitigated by the fact that soil microorganisms continue mineralizing plant debris over the long winter so that at flushing after snowmelt there is a short peak of high nutrient availability, including those nutrients which had accumulated in snow and become available with melt water. In such seasonal climates alpine plants must be specialized to capitalize on such nutrient peaks. In tropical alpine environments, the “endless” season, can somewhat compensate for the slow microbial nutrient provision.

Alpine Plant Life

How specialized are alpine plants to cope with alpine life conditions? From a physiological perspective, less than one would expect. Since plants photosynthesize only during light hours, the warm canopy conditions described above explain why CO₂ uptake

Fig. 3 The temperature in an alpine inflorescence under sunny weather conditions. Note the heated center where ovaries are located and where seeds will develop (Dietrich and Körner, 2014).

reaches a peak at roughly the same temperatures as in their lowland relatives (Körner, 2003). There is sound evidence that strong solar radiation does no harm to alpine plants, including UV-radiation (Lütz, 2012). Freezing tolerance is so high during the dormant season that winter is not an issue. Frost events can damage leaves and flowers during the growing season, yet the flora of the alpine biome is well adapted to cope with such events (Taschler and Neuner, 2004; Larcher et al., 2010; Ladinig et al., 2013). Since most alpine plant species grow clonally and thus live very long (potentially millennia), they do not depend on regular sexual reproduction, hence episodic losses of inflorescences or premature seeds are not fatal to them.

In contrast to photosynthesis (carbon uptake during the day) the investment of carbon into growing tissues is constrained by low temperatures, particularly during the night. Yet alpine plants can build new cells at substantial rates when temperatures are as low as 5°C, a temperature at which lowland plants (or crops) would scarcely grow. Alpine plants may even grow very slowly down to 0°C, but they take no advantage for growth from tissue temperatures above 15°C, as lowland plants do (Nagelmüller et al., 2017). Alpine plants thus utilize the short warm periods for growth, requiring very rapid development in cases where the season is very short. This calls for an adapted phenology, that is the seasonal succession of developmental events such as leaf expansion, flowering, fruiting, and controlled senescence and dormancy transition. However, there is a high diversity in alpine phenology, with some species ready to flower even before snow disappears and others flowering only very late in an otherwise short summer. Seed maturation must complement these rhythms of life. This life event shows a great deal of flexibility in alpine plants (e.g., Molau, 1993; Wagner et al., 2010).

The Alpine Biome Under Global Change

With its global occurrence, the alpine biome is particularly interesting for monitoring the influences of environmental changes at a large scale. Yet there are some misconceptions associated with the potential hazards of global warming on alpine ecosystems. Because of the central role of topography for shaping actual life conditions and because of the evolutionary adjustment to these many microclimatic niches in an alpine landscape, the alpine biome is possibly the safest of all biomes when the climate changes (Scherrer and Körner, 2011). Nowhere else can organisms escape from “unpleasant” locations faster and over shorter distances than in topographically structured alpine terrain. So there is little evidence that alpine ecosystems and alpine organisms are particularly vulnerable to climatic warming.

This does not mean that at a local scale a finely tuned interplay between plant and animal activity may easily escape from climate change driven running “out-of-phase.” Yet, at a scale of a few km² such problems will become greatly moderated by topographic diversity. Perhaps the most damaging change will be a shortening of snow duration for plants and animals that require snow protection. So changes in precipitation, especially in snowfall, are likely to have greater impacts than changes in temperature as such. At a global scale, there is a trend for increasing precipitation with increasing atmospheric temperature. So regionally snow pack may even increase (particularly at very high elevation) despite climate warming. There may be more frequent summer drought in some areas, the effect of which will depend on season length and soil depth. With a short season and deep soils, temperate, and subarctic alpine ecosystems are unlikely to experience fatal drought during dry episodes. However, Mediterranean alpine ecosystems might be impacted. There is evidence that the arrival of new species on high mountain summits has increased in recent years in the temperate zone, but it has decreased in the Mediterranean (Pauli et al., 2012; Gottfried et al., 2012). Mobile animals (birds and insects) respond faster than plants (Roth et al., 2014).

Less widely acknowledged are changes of global dimensions such as the steady rise in atmospheric CO₂ concentrations (a potential driver of photosynthesis) and atmospheric nitrogen deposition (a fertilizer). Because growth in alpine plants is (a) intrinsically slow, (b) limited by low temperature, and (c) strongly limited by the availability of a broad spectrum of soil nutrients, it is not surprising that in situ exposure to elevated concentrations of CO₂ over several growing seasons has no stimulating effect on plant growth (Körner et al., 1997; Inauen et al., 2012). So alpine plants do not seem to be carbon limited at the current atmospheric CO₂ concentrations.

In contrast, the addition of soluble nitrogen compounds is potentially very harmful, because freely available nitrogen is known to shift the competitive balance among species, with fast growing, “trivial” species outcompeting slow growing rare species (Bobbink et al., 2010). A trivialization of the flora during recent years had been documented for the Swiss forelands of the Alps (Roth et al., 2013). Although atmospheric loading with soluble nitrogen compounds from fossil burning had been reduced by employing catalysers in cars, emissions from intense agriculture has increased in many areas at the same time. While high mountain terrain is commonly less loaded, these nitrogen-limited ecosystems are particularly sensitive to N additions and depositions as low as 5–10 kg N ha⁻¹ a⁻¹ were found to exert significant changes (hence surpass what is considered a critical load; Bobbink et al., 2010).

At a global scale, land use and land transformation are possibly the most severe facets of global change in the alpine biome. With herding and fire, many high ecosystems become over-utilized and destroyed in some parts of the world, and under-used or rapidly abandoned in other parts. Although the most severe impacts occur in the upper montane (often deforested) belt, these activities reach into the lower part of the alpine biome, and once land becomes scarce at lower elevations the herders move to the alpine proper. Millennia of land use continues to impact many high elevation and alpine ecosystems globally (e.g., Noroozi and Körner, 2018; Monteiro and Körner, 2013; Miehe et al., 2019). These direct impacts on the alpine biome can be mitigated or reverted at local or regional scale, while the global atmospheric changes are beyond the reach of local stakeholders.

Abstract

The páramo landscape consists of natural grasslands above the closed forest line (generally at 3000–3500 m asl—above sea level) and below the glaciers (4500–5000 m asl), where these are present. They cover ~35,000 km² extending across Venezuela, Colombia, Ecuador, and northern Peru and a number of small patches between Costa Rica and Panamá. They constitute an ecological archipelago, distributed along the highest parts of the northern Andes. The vegetation is subjected to large daily temperature fluctuations, and mist cover alternates with high solar irradiation. Therefore, organisms have developed unique adaptive strategies to cope with abiotic conditions in this extreme environment, leading to important processes of speciation and evolutionary convergence. This has resulted in high endemism and a remarkable plant diversity, the highest among all alpine landscapes in the world (Fig. 1).

Páramos provide a range of ecosystem services that created a large social basis for its conservation, especially for water regulation. However, human activities, including agriculture, cattle grazing and mining, impact their capacity to provide benefits for the wider society. The current configuration and diversity of páramo cannot be assessed without considering its coexistence, positively and negatively, with human society. This situation is even more dynamic considering the yet little understood impact of global climate change. High mountain ecosystems are among the most exposed and vulnerable in the world to the effects of global warming and páramo is no exception. However, there is still a large knowledge gap about the actual effects on local temperature regimes and precipitation patterns and therefore, the associated impact on the ecosystem, its vegetation and society remain little understood.

Introduction: Description and Distribution of Páramo

The highest parts of the wet perhumid northern tropical Andes consist of fragile landscapes characterized by a high biodiversity (Körner and Spehn, 2002; Price, 2006). These ecosystems include alpine páramo grasslands and humid montane cloud forests, which originally covered large tracts in Venezuela, Colombia, Ecuador, and Peru. The páramo landscape consists of natural grasslands above the closed forest line and below the glaciers, where these are present. They cover ~35,000 km² extending across Venezuela, Colombia, Ecuador, and northern Peru (11° North to 8° South), and a number of small patches (less than 20,000 ha in total) between Costa Rica and Panamá (Fig. 2, Cuesta et al., 2014; Hofstede et al., 2003, 2014a,b; Llambí and Cuesta, 2014; Luteyn, 1999).

The South American páramos constitute an ecological archipelago, distributed along the highest parts of the northern Andes. In this insular environment, landscape diversity is high, because the Andes are relatively young in geological history, molded both by volcanic and glacial/periglacial activity, and distributed along wide elevation and latitudinal gradients. The vegetation is subjected to large daily temperature fluctuations, and mist cover alternates with high solar irradiation. Therefore, organisms have developed unique adaptive strategies to cope with abiotic conditions in this extreme environment (Azócar and Rada, 2006; Rada, 2016), leading to important processes of speciation and evolutionary convergence (Cuatrecasas, 1958; Hedberg and Hedberg, 1979; Monasterio and Sarmiento, 1991; Van der Hammen and Cleef, 1986). This has resulted in a high level of endemism and remarkable plant diversity. It is well documented that this tropical alpine zone is the richest in terms of plant diversity among all alpine landscapes in the world (Smith and Cleef, 1988; Cuesta et al., 2017). The páramo also exhibits an outstanding functional plant diversity (Llambí et al., 2014), reflected in a wide range of plant growth-forms including giant rosettes, sclerophyllous shrubs, tussock grasses, nongraminoid herbs, cushion plants and acaulescent rosettes (Hedberg and Hedberg, 1979; Ramsay and Oxley, 1997).

Páramo is of high social and economic importance, because it provides important ecosystem services, particularly the regulation of water for human consumption and irrigation (Buytaert et al., 2006; Buytaert and de Bièvre, 2012). While these ecosystem services helped to create a social basis for its conservation (Llambí et al., 2005; Sarmiento et al., 2017), other uses of páramo, including agriculture, cattle grazing and mining, affect their capacity to provide benefits to the wider society. Inhabitants of these regions reflect complex cultural and socio-economic conditions. While intensive potato-farming is present in easily accessible páramo around major population centers, many and more remote communities are made up of indigenous peoples and mestizo farmers that rely almost entirely on the natural resources of páramo, principally for agricultural production (Cuesta et al., 2012a,b; Ange-Jaramillo et al., 2002;

Hofstede, 2011; Sarmiento et al., 2017). All of these human uses have developed in a haphazard way, and are steadily affecting more areas. The current ecological conditions and biological diversity of páramo cannot be assessed without considering its coexistence, positively and negatively, with human society. This situation is even more dynamic because of the still poorly understood impacts of global climate change. High mountain ecosystems are among the most exposed and vulnerable to the effects of global warming and páramo is no exception (Castaño-Urbe, 2002; Cuesta et al., 2008; Tovar et al., 2013; Vuille et al., 2018). However, there is still a large knowledge gap concerning the actual effects of global change on páramo temperature regimes and precipitation patterns (Tovar et al., 2013; Ramirez-Villegas et al., 2014; Morueta-Holme et al., 2015).

Biogeography

The heterogeneity of the páramo landscape reflects the diverse abiotic, biotic, and anthropogenic processes (Llambí and Cuesta, 2014). The Northern Andes consists of three (northern portion) and two (central portion) *Cordilleras* (mountain ranges), divided by inter-Andean valleys. Climatic processes, such as the humid currents from the Amazon basin and the Equatorial Tropical Pacific (Humboldt), drier currents from the Caribbean and the Southern Tropical Pacific (Nazca), cloud cover and main wind directions give rise to more-or-less humid slopes and valleys, determining the characteristics of each of páramo zone (Rivera and Rodríguez, 2011). Present-day geological (vulcanism, glaciation) and geographical aspects (geomorphology, drainage, soils) determine different types of páramo, even at the local scale. Biogeography (origin, distribution, connectivity, and radiation) is another aspect that determines biodiversity and the classification of different páramos (Jørgensen and Ulloa, 1994). Finally, the type and degree of human intervention is an additional factor that determines the actual structure and functioning of páramo.

Different authors have proposed different classifications of páramo types, depending on geographical distribution, altitudinal zonation, vegetation physiognomy, climatic regime, and conservation status. The best known is the one proposed by Cuatrecasas (1958), based on a division into altitudinal belts: subpáramo (the lower, shrub-determined zone, understood as a transition between the mountain forest and open páramo, Fig. 3), páramo proper or grass-páramo (the typical páramo landscape, dominated by tussock grasses and giant rosettes, Fig. 1) and the highest-elevation super-páramo (a more open vegetation without full soil coverage and a high abundance of prostrate shrubs and herbs, cushions, lycopodia and lichens, Fig. 4).

Climatic processes are the basis for a bioclimatic classification of dry páramo, semi-humid, humid, very humid, super humid, and pluvial páramo (Rangel, 2000). The World Wildlife Foundation (WWF) proposed an ecoregional classification, distinguishing four different páramo ecosystems on the basis of their geographic situation on the Andean mountain ranges (Cordillera de Mérida páramo, Sierra Nevada de Santa Marta páramo, Cordillera Central páramo and Northern Andes páramo (Dinerstein et al., 1995). These bioclimatic and biogeographic classifications were combined by Josse et al. (2009) to devise a more detailed ecosystem classification at the scale of the Northern and Central Andes (from Bolivia to Venezuela). Within their Northern Andes phytoregion, three exclusive páramo macrogroups were identified. These were further subdivided into six ecosystems for páramo proper, three páramo wetland ecosystems and one ecosystem for superpáramo. This classification included the traditionally considered subpáramo or shrub páramo within the macrogroup of humid high Andean forests and shrublands.

Fig. 1 Páramo proper (or grass páramo) vegetation with stem rosettes (*Espeletia hartwegiana*) and tussock grass (*Calamagrostis effusa*). In the background, shrub dominated sub-páramo and high Andean forest (Los Nevados National Park, Colombia; 3600 m asl).

Other authors used social and land use characteristics to describe different páramo types. Using a socio-ecosystem approach, [Monasterio and Molinillo \(2003\)](#) redefined the classic altitudinal zonation by Cuatrecasas, using a combination of natural and cultural characteristics. Their *piso andino* (or Andean belt) corresponds to the high mountain forest and lower páramo life zone and is characterized by highly productive crops (Andean tubers, fresh vegetables, flowers, etc.) that replace the natural páramo systems, especially in flat and more fertile areas. The *piso altiandino* (or high Andean belt) corresponds to the páramo proper belt where the upper agricultural limit is found, with an alternating system of crop planting and fallow lands which promotes successional processes leading to ecosystem regeneration. This area is naturally covered by tussock grasses and stem rosettes. Above the crop line, the only anthropogenic land use is extensive livestock grazing. At higher elevations they defined the *piso periglacial* (periglacial belt), where frequent night frost events impede agricultural activity and where the vegetation types are called the desert páramo and periglacial desert. Finally, [Hofstede et al. \(2002\)](#) proposed a categorization for health status of tussock-grass dominated páramo, describing five classes (from “poor” to “excellent” health condition) based on flora, fauna, and soil characteristics that, combined with social indicators, helped to determine the degree of disturbance.

Geological History

Páramo is a relatively young ecosystem; it might even be considered the youngest of all Andean ecosystems ([Castaño-Urbe, 2002](#); [Van der Hammen and Cleef, 1986](#)). The history of neotropical vegetation begins ~100 million years ago (Ma), when the South American continent separated from Gondwana. The uplift of the Andes initiated 40 Ma and during the Miocene, 10 Ma, the mountain range started to take its current shape and individual mountain massifs were connected, allowing for migration of plants from

Fig. 3 Lower elevation páramo (sub-páramo) dominated by shrubs and low trees (Sangay National Park, Ecuador; 3600 m asl).

Fig. 4 Higher elevation páramo (super-páramo) dominated by herbs, ground rosettes and cryptogams (Pichincha volcano, Ecuador; 4300 m asl).

the Southern (colder) mountain environments to the North. Also around that time, South America became connected to North America through the Panama Isthmus. After this, during the Miocene, several Holarctic taxa entered South America and the Andes continued to arise (Gentry, 1982). During the Pliocene, between ~ 5 and 2.5 Ma, there was abundant volcanic activity, at which time elevations above the treeline came into being. Only then the Andean range reached its current elevation, with relatively large areas covered by open vegetation above the continuous forest line (Morales et al., 2007). The landscapes above treeline connected with Northern and Southern temperate zones, creating the environment in which the current páramo vegetation could evolve.

The upper Andean forest and páramo belts evolved more or less simultaneously during this period and in the Early Pleistocene (4–2 Ma), and an early páramo vegetation (proto-páramo) developed. The early tropical biogeographical elements were species from lower (forest) environments that became adapted to the environment at higher elevation. The largest diversity of these elements is found in the Northeastern-most extension of the Northern Andes, the Cordillera de Mérida, near the Venezuela-Colombia border, which is geologically the oldest part of the Northern Andes. Some typical páramo genera like *Espeletia* have their centers of speciation here (Pouchon et al., 2018). Other genera migrated from the more temperate regions to the north and south,

Fig. 5 Indigenous páramo inhabitants (Chimborazo, Ecuador).

Fig. 6 Cattle grazing has transformed stem rosette and tussock grass dominated páramo proper in a compact, short mat of ground covering grass (Tolima, Colombia).

giving rise to an early vegetation of Poaceae, Cyperaceae, Asteraceae, and Ericaceae, among others (Van der Hammen and Cleef, 1986). During this time, genera of north temperate origin (*Alnus*, *Quercus*) also entered the Andean forest, signaling the next phase in connectivity between the Northern and Tropical cool biomes (0.3 Ma; Luteyn, 1999).

During the Pleistocene, glacial periods alternated with interglacial periods, with some severe cold periods. At that time there were numerous changes in the proportions of landscape cover between páramo and forest elements, although the páramo flora was already well established and probably dominated. There was a cold and wet period during which the last glaciation reached its maximum advance (42,000–25,000 BP), during which the glaciers and forest may have been connected at elevations between 2200 and 2700 m asl and the páramo belt must have been narrow and wet (Van der Hammen and Cleef, 1986). In contrast to this, between 21,000 and 14,000 BP there was a very cold but dry period. At that time glaciation was not so extensive, and the páramo belt was broad and covered most of the area above 2000 m asl. (Luteyn, 1999). At the beginning of the Holocene (13,000 BP) the climate became warmer and forest limits rose to elevations even higher than today. At that time, the páramo became restricted to the highest parts of the Andean mountain range. Finally, at about 2900 BP there was a remarkable climatic cooling that marked the last downward movement of the forest and páramo belts to their present-day positions (Wille et al., 2002). This series of past climatic changes and associated lowering and rising altitudinal belts and the narrowing and widening of areas occupied by páramo, caused páramo patches to be connected and separated repeatedly (Flantua and Hooghiemstra, 2018). It is expected that during colder periods, in which páramo occupied larger areas, the connectivity resulted in the rapid expansion of species over the Andes, while

Fig. 7 Potato cultivation and grazing of fields in fallow has transformed the páramo landscape in a mosaic of different levels of intervention that, in this case, led to low biodiversity and clear signs of land degradation (Guerrero, Colombia).

during warmer periods, many páramo areas were isolated from each other, resulting in species radiation. A spectacular example of this process involved the stem rosettes of the *Espeletia* complex, which is the fastest adaptive radiation recorded for plants (Díazgranados and Barber, 2017; Hofstede et al., 2014a,b; Madriñán et al., 2013; Pouchon et al. 2018). Therefore, the present páramo flora has many tropical as well as boreal elements, with genera that are relatively common (Sklenář et al., 2005) but with an extremely high level of species endemism (Luteyn, 1992).

Connectivity and Isolation

The historic rhythm of connectivity and isolation of different páramo regions contributed to species distribution and radiation (Van der Hammen and Cleef, 1986; Flantua and Hooghiemstra, 2018). Nowadays, páramo forms an ecological archipelago, distributed along the highest parts of the northern Andes, like a “chain of pearls” (Balslev, 2001). In total, it occupies $\sim 35,000 \text{ km}^2$ (Llambí and Cuesta, 2014). The northernmost páramo areas are the isolated complex at the Sierra Nevada de Santa Marta, in Colombia, and the small areas on top of the Talamanca mountain range in Costa Rica. Due to their isolation, both have a specific flora and fauna. The páramos in the Colombian Western Cordillera form isolated small patches that might have been connected in the past.

In the North of the Andean corridor is a large connected páramo complex in the Mérida Cordillera in Venezuela. From Tamá (the transborder páramo between Colombia and Venezuela) down to the Sumapaz massif south of Bogotá, there is a large and, in many areas, connected complex that covers the Colombian eastern Cordillera. The Central Cordillera, its southern continuation in the Colombian Massif, and the entire Ecuadorian Cordillera are of volcanic origin, resulting in a large mountain range of diverse maximum elevations. There are large, but separated complexes of páramo in the Colombian Nevados, the páramo of Las Hermosas, the páramo of the Colombian Massif and the Southernmost páramos, connected to the North Ecuadorian páramos of Carchi and Nariño. Within the Ecuadorian volcanic mountain ranges, the largest connected complex of páramos are found, covering the entire Eastern, or Cordillera Real, from the Cayambe Volcano down to the Sangay National park, only interrupted by the Ambato river valley. In the Ecuadorian Western Cordillera large but separated páramos complexes are found around the Cotacachi, Pichincha, Ilinizas, and Chimborazo volcanoes. In Southern Ecuador, where the Andes are older, and consist of heavily glaciated metamorphic geology, a large separated páramo complex is found west of the city of Cuenca (El Cajas). The Southernmost páramo extension is again a connected, but very narrow páramo covering the lower and wet páramo of the Cordillera de Sabanilla down to the Valley of Huancabamba (Hofstede et al., 2014a,b). The latter is generally considered as the biogeographical limit between the Northern and the Central Andes (Jorgensen and Ulloa Ulloa, 1994). South of the Huancabamba valley, a similar, but more seasonal ecosystem continues, locally known as Jalca.

The present pattern of connectivity and separation is being affected by human impact. In several areas the páramo has disappeared after transformation to productive grassland, potato fields or industrial pine plantations. This artificial separation has caused interruption of natural larger páramo complexes. On the other hand, large scale burning of páramo and Andean forest caused a downward movement of páramo vegetation, covering areas that were naturally covered by Andean forest (Ellenberg, 1979; Laegaard, 1992). This artificial lowering of the forest line caused an extension of the páramo biome (“paramisation”) and therefore

greater connectivity in certain areas. Normally, these areas are used for extensive animal husbandry that includes repeated burning. Therefore, the larger páramo extension through “paramisation,” and its associated connectivity, provide little possibility for native flora to expand and disperse to other areas and the most valued páramo plant and animal species disappear from these new páramo extensions (Hofstede et al., 2002).

The geological history of the Andes determined the origin of the páramo flora. The early uplift of the Andes (40 Ma) happened in a tropical environment without any connection with area of cooler climate. Therefore, the first elements of the páramo flora evolved from tropical ancestors. The result of this history is a páramo flora that, in terms of genera, consists of 7% páramo elements (genera endemic to the ecosystem), 34% Neotropical, 9% Austral-antarctic, 11% Holarctic, 21% broad temperate, 10% broad tropical, and 8% cosmopolitan. This means that, ~45% of all genera are of temperate origin and 45% are of Neotropical origin (Van der Hammen and Cleef, 1986).

The páramo endemic genera most likely originated in the Pliocene, while the immigrant genera would have arrived during the late Pliocene and Pleistocene. The characteristic caulescent rosette genus *Espeletia* originated in tree-like *Espeletiinae*, and it speciated during the Pleistocene to more than 150 extant species, the fastest adaptive radiation recorded for plants (Diazgranados and Barber, 2017; Morales et al., 2007; Pouchon et al., 2018; Van der Hammen and Cleef, 1986). The taxonomic group *Espeletiinae* was originally formed in the Venezuelan Andes (close to the border with Colombia), where the *frailejones* group (*Espeletia*-*Espeletiinae*) has a large number of endemic species. This is the oldest geological formation that harbors páramo and is the center of diversification and expansion (Cuatrecasas 1958; Pouchon et al., 2018; Smith and Koch, 1935). *Espeletia* is the largest evolutionary and adaptation “success” in the occupation of the most extreme environments (in terms of climatic conditions): its diversity in terms of form and function permitted *Espeletia* to occupy a wide range of habitats. It currently occupies habitats in all different páramo types between Venezuela and the North of Ecuador (Cuatrecasas 1958; Van der Hammen and Cleef 1986; Monasterio and Sarmiento 1991; Rada, 2016). Moreover, giant rosettes of the *Espeletia* complex have been shown to act as ecosystem engineers in the harsh superpáramo environments, improving local microhabitat conditions (including marked increases in soil organic matter), and having a positive-facilitation effect on the cover and species richness of many other páramo plants (Mora et al., 2018).

Plant Richness and Endemism

According to Luteyn’s (1999) checklist of páramo plants, there are approximately 3400 species of vascular plants and 1300 of nonvascular plants in the entire páramo biome. Sklenář et al. (2005) reports 3595 species of vascular plants in 127 families and 540 genera, 14 of which are endemic to the Northern Andes. Rangel (2000) estimated that the total number of páramo vascular plant species is at least 4700. The relatively large difference between these total numbers of species can be explained by different concepts of the split between Andean forest and páramo species or, in other words, where to place the virtual division line in the Andean forest—subpáramo ecotone.

The most species-rich families (including their approximate numbers of genera and species) are Asteraceae (100 genera and 710 species), Orchidaceae (57 genera and 580 species), Poaceae (40 genera and 150 species), Melastomataceae (12 genera and 110 species), and Bromeliaceae (7 genera and 100 species). Genera with the highest number of species (approximate numbers) are *Epidendrum* (Orchidaceae; 105 species), *Espeletia* (Asteraceae; 80 species), *Pleurothallis* (Orchidaceae; 80 species), *Diplostephium* (Asteraceae; 75 species), *Miconia* (Melastomataceae; 65 species), *Hypericum* (Hypericaceae; 55 species), *Monticalia* (Asteraceae; 55 species) y *Baccharis* (Asteraceae; 55 species) (Cuatrecasas, 1958; Luteyn, 1999; Rangel, 2000; Sklenář et al., 2005; Van der Hammen and Cleef, 1986). This list indicates that the taxa characteristic of the open, grassland-dominated páramo vegetation are included (Poaceae, Asteraceae, *Espeletia*, *Hypericum*), but most are taxa typical of the lower, shrub-dominated páramo (Orchidaceae, Melastomataceae Bromeliaceae, *Baccharis*). This reflects the trend that species richness generally decreases with increasing elevation. The highest species diversity is found between 3000 and 3400 m asl; above 4000 m asl, the number of species decreases (Beltrán et al., 2009; Cuesta et al., 2017).

The number of genera endemic to the páramo ecosystem is relatively low, but endemism at species level is very high (Luteyn, 1992; estimated at 60%, again depending on where the virtual division-line between Andean forest and páramo is placed). This is explained by the relatively young geological age of páramo. Specific endemism for the total area is high, but even higher for geographically isolated areas, like many of the páramo communities in Colombia and the Ecuadorian Western Cordillera (Luteyn, 1999). Also, endemism increases with increasing altitude and superpáramo has few species, but many are not found anywhere else in the world (Sklenář, 2000). The high and singular biodiversity is related to the diversity of ecological conditions created by a complex topography and glacial geomorphology (Llambí and Cuesta, 2014) resulting in a large number of different vegetation associations, each of which has its own species assembly (Rangel, 2000).

Rangel (2000) mentions 118 families, 567 genera, and 3380 species, just in Colombia. For the Ecuadorian páramo, a total of 1524 species of vascular plants have been reported, which is half the number of Colombian species in a similar-sized area. This can be attributed to lower degree of isolation of the Ecuadorian páramo complexes and their greater distance from the origin of radiation of páramo species in Venezuela-NE Colombia (Beltrán et al., 2009; León-Yáñez, 2011). In Ecuador, 628 species are endemic to the páramos which represents 15% of the total flora endemic to Ecuador. In addition, 75% of the species that are endemic to Ecuadorian páramos are considered endangered and only 48% of them are in protected areas (León-Yáñez, 2011). The Venezuelan páramo has 1420 species in an area five times smaller than that of Colombia or Ecuador (Briceño and Morillo, 2002). Two reasons explain the high species richness and endemism here: first, the Mérida Cordillera has high habitat

diversity with contrasting habitats and landscapes where cryothermic deserts mingle with wetlands. Second, this region is the center of diversification for páramo flora (Rodríguez and Rojas-Suárez, 1995; Pouchon et al., 2018). Due to its closeness to the Southern Andean region, the páramo flora of Perú is characterized by species associations that differ from those of other Andean countries. Besides typical páramo grass and grass-like genera (*Calamagrostis*, *Festuca*, *Stipa*, *Carex*), there are more taxa of southern origin, such as *Cortaderia*, *Chuquiraga* and shrubs in the Podocarpaceae (Novoa et al., 2011). In one single páramo complex in the Northern Peru (Pacaipampa) 116 vascular plant species were found, 51 of which are endemic to the area (Cuesta et al., 2012b, 2017). In Costa Rica, more than 350 species of vascular plants were identified, in addition to 230 bryophytes and 215 lichens (Kappelle, 2003).

Impact of Human Activities on Páramo Plant Diversity

Páramo has been used by people ever since the early days of human occupation of the South American continent (10,000 years BP). Although during most of this time, use was very low in intensity, due to the long interaction between people and páramo, the natural ecosystem has been altered and cultural diversity coexists with natural diversity; therefore, páramo should be interpreted as a socio-ecosystem. The history of human occupation of páramo has very different characteristics over time: during prehispanic times páramo was only used for communication, occasional hunting-gathering and water harvesting. During Spanish colonial times, it began to be used intensively for large-scale sheep grazing and wheat cultivation for export to Europe. After the agricultural reforms of the mid-20th Century, large *haciendas* were split up, and land use was diversified and the previously marginalized indigenous groups and displaced farmers chose páramo as permanent habitat for living and farming (González and Cárdenas, 1995; Hofstede et al., 2014a,b; Reyes, 1995; Molano, 2010; Monasterio, 1980; Recharte and Gearheard, 2001; Fig. 5). Originally, small scale land-use was developed at the lowest elevations and was of low impact; in fact, the existence of small-scale farming communities who benefitted from the use of the natural ecosystems added to overall landscape diversity and created a socio-ecosystem of coexistence that fostered large cultural and biological diversity (Maldonado and De Bievre, 2011). However, due to different social changes, such as marginalization, environmental degradation, climate change, and political initiatives, such as agricultural reform, the human communities encroached on the Páramo, and natural grasslands became increasingly transformed to agricultural fields. Even more damaging has been the intensive use of páramo for large scale, industrialized potato cultivation, mostly financed by city-based companies and landowners (Machado et al., 2010; Monasterio and Molinillo, 2003; Sarmiento et al., 2017).

The result of the history of human occupation is that nowadays, there are different levels of intensity of páramo use, depending on the region. Meanwhile, there are also still large areas of páramo with very little human impact because they are too wet, too inhospitable, or lack easy access. In total, 35% of páramo is included in protected areas (Hofstede et al., 2014a,b). The different land use types and intensities in this landscape result in a mosaic of different habitats, caused by high levels of patchiness of landscape elements. In some areas, this impact of land use contributes to the landscape diversity, but in others it constitutes the main threat to its existence (Hofstede, 2001; Monasterio and Molinillo, 2003).

The main agricultural activities affecting páramo vegetation are cattle grazing (Fig. 6) and its associated burning, and potato growing (Fig. 7). The impact of grazing on the ecosystem depends on the type of animal and its stocking rate. Páramo evolved without a high biomass of large herbivores and therefore, its vegetation is not adapted to grazing. Some growth forms, such as tussock grasses and ground rosettes, are able to tolerate moderate levels of grazing but others, particularly introduced stoloniferous species such as *Holcus lanatus* and *Pennisetum clandestinum*, tolerate grazing and trampling much better. Therefore, with higher grazing densities, these plants tend to increase in the landscape. Other native páramo species, particularly shrubs and endemic super-paramo herbs, are intolerant to grazing and trampling and tend to decrease their abundance or disappear. As a result, grazing affects the structure (more open, less tall) and composition of the vegetation (more creeping, stoloniferous, more exotic species and less shrubs and endemic herbs; Verweij, 1995; Molinillo and Monasterio, 1997, 2006).

In many regions, it is impossible to consider grazing independently from burning (except in the Venezuelan páramos, where burning is not a practice associated with cattle management). In most areas where páramo is used for cattle grazing, farmers tend to burn the tall tussock grass vegetation to provide the cattle with better access to regrowth (Hofstede, 1995; Vargas et al., 2002). These fires affect different species differently: some species tolerate moderate intensity and frequency of fires, such as tussock grass, creeping herbs and shrubs, but others are strongly affected, such as most woody plants and several native herbs. Therefore, with repeated fires the vegetation structure and composition changes (Laegaard, 1992; Verweij, 1995). The combination of grazing and burning has a synergistic effect. Research has identified areas with low grazing intensity and burning frequency, where the total number of species is higher than in natural páramo areas. However, when the species composition is considered, it becomes evident that several typical páramo species have disappeared from burnt and grazed areas, while new species (mostly exotics) have appeared. In areas of high grazing and burning intensity the number of species decreases, but vegetation cover is also less complete, contributing to soil erosion (Hofstede, 2001; Poulenard et al., 2004; Verweij, 1995).

Potato cultivation is widespread in several páramo regions, up to 4000 m asl. In most cases, cultivation is being rotated with animal husbandry: after 2 or 3 crops, the area is left for recovery, sowing grass for grazing. Traditionally, the fallow time was up to 20 years. However, recently, this has become as short as 3–5 years (Sarmiento and Llambí, 2011). Also, improved technologies and climate change have opened more páramo areas for potato cultivation (Morales et al., 2007). For cultivation, the entire natural vegetation cover is removed. Subsequent recovery of the natural vegetation after agricultural use depends on the length rotation time and on the style of land management. If the cultivated plots are large, rotation is short and during the fallow interval the landscape is used for dairy cattle, feeding on exotic grasses. Under these circumstances there is little chance of natural vegetation recovery.

On the other hand, in Venezuela several studies have analyzed semi-traditional system of páramo cultivation, with low intensity, varied crops and long fallow periods. This has resulted in a stable and acceptable level of restoration of nutrient cycling and plant diversity (Abadín et al., 2002; Llambí et al., 2003; Llambí and Sarmiento, 1998; Sarmiento et al., 2003; Sarmiento and Llambí, 2011). These studies showed that, contrary to the general belief that high Andean ecosystems are highly vulnerable, with low resilience, in fact with long fallow intervals (more than a decade) páramo does recover a considerable proportion of its plant species and plant community structure. However, some species will never recolonize the previously used parcels and alpha biodiversity is lower than before land use (Sarmiento et al., 2002, 2003).

High mountain ecosystems are generally considered among the most vulnerable to the effects of climate change. The aspects of climate change that potentially have an effect on páramo vegetation are increased temperatures, changes in precipitation regimes and higher irradiation. This can have an effect on the position of altitudinal belts, causing the disappearance of species that do not tolerate the new environment, combined with the appearance of species that better tolerate the new conditions. The new environmental conditions also favor increased human land use, with upslope shifts in agriculture, affecting the vegetation (Araujo and Rahbek, 2006; Anderson et al., 2011; Cuesta et al., 2012a). The upward movement of altitudinal belts, deforestation and agricultural activity at higher areas, in combination with the phenomenon of “paramisation” (fire-induced lowering the forest line) has caused that currently, in most high mountain areas it is impossible to identify the natural upper forest line (Hofstede et al., 2014a,b; Llambí et al., 2014).

At the species level, there are three responses to climate change: migration, adaptation or local extinction. An interaction between the three can be expected in mountain areas: an accelerated upslope migration of vegetation belts can result in immediate local extinction as well as impacts on phenology and physiology of species (Buytaert et al., 2010; Cuesta et al., 2012b; Parmesan and Yohe, 2003; Tovar et al., 2013). It is assumed that high mountain plant species are particularly sensitive to climate change because they have specific adaptations to extreme climatic conditions. If these conditions change, their developed adaptation gives them less competitive advantage. Also, mountain ecosystems have a limited range; their populations are fragmented, and species have many barriers to migrate to other areas (Bendix et al., 2013; Grabherr et al., 2010). If the patterns of climate change effects on vegetation in the páramo are similar to those observed in other mountain regions in the world (Peñuelas and Boada, 2003; Pauli et al., 2007; Sanz-Elorza et al., 2003), the species related to the highest-elevation vegetation belt (superpáramo) should be the most threatened (Buytaert et al., 2006; Cuesta et al., 2017).

Based on species distribution and climate models, it was estimated that ~60% of all páramo plant species will have populations heavily reduced or become extinct by 2080 (Cuesta et al., 2008, 2012b). However, as these same authors admit, it is risky to make estimates of extinction patterns based on future climate and vegetation distribution models, considering there is a high difference between different warming scenarios and there is little knowledge on the actual response of species to changing climatic conditions (Buytaert et al., 2010). To fill this knowledge gap, there is a wide network of GLORIA sites in the Tropical Andes (Cuesta et al., 2012b, 2017).

A recent study comparing historical vegetation records made by Humboldt during the 19th century with recent surveys of the vegetation of the Chimborazo volcano, suggest there has been an upward migration of many plant species associated with temperature warming (Morueta-Holme et al., 2015). Similar conclusions have been derived for Carabidae beetles based on more recent diachronic studies (Moret et al., 2016). So far, the few available empirical and theoretical studies from the paramos reinforce the idea that the loss and fragmentation of habitat exacerbate the risk of extinction of mountain species due to climate change (Larsen et al., 2011). However, more long-term, comparative field monitoring is essential to document the effects of climate change on high elevation páramo plant communities. Ongoing surveys within the system of permanent plots established in high mountain summits during the last decade by the GLORIA-Andes network will undoubtedly make an important contribution towards this goal (Cuesta et al., 2012b, 2017).

Glossary

Afro-alpine Zone A vegetation zone situated between the Giant Heath Forest and Nival Zones to the highest mountains in tropical Africa, characterized by strong diurnal variation in temperature.

Fromontane The phytogeographic “catch-all” for the archipelago-like moist upland vegetation scattered in sub-Saharan African and characterized by montane forests and grasslands rich in local and regional endemism.

Bio-temperature The mean value of daily mean temperature above 0°C divided by 365.

Ecotone An intermediate zone between two different ecological communities.

Endemic A taxon unique to a defined area; confined to a certain area.

General dynamic model A model that links the geomorphological life cycle of volcanic oceanic islands (from original emergence to submersion) to that of island species richness and endemism (through colonization, speciation and extinction).

Giant Groundsel The genus *Dendrosenecio* (Asteraceae), endemic to the tropical African mountains, and found at high elevation regions (>2500 m) in the Giant Heath and Afro-alpine Zones—typically the “flagship” genus of the Afro-alpine Zone although the genus is not endemic to this Zone.

Giant Lobelia A subset of the genus *Lobelia* (Campanulaceae) that have attained giant proportions, occurring in moderate to high elevations (>1300 m) in tropical Africa, Oceania and southeast Asia.

Páramos The Andean tropical alpine equivalent to the Afro-alpine, and characterized by giant forms similar to those in the Afro-alpine (although unrelated genetically); occurs from 2800 to 4700 m elevation.

Phylogenetics The study of the evolutionary history and relationships among individuals or groups of organisms.

Phytogeography The study of the geographic distribution of plant species and explanations thereof.

Speciation The biological process by which new species develop.

Species complex A group of species with unclear taxonomic boundaries, often due to intergrading morphological characteristics.

Tropical Alpine Zone The highest elevation regions within the tropics but below the Nival Zone; usually between 3200 and 4500 m elevation.

Abstract

The Afro-alpine Zone is a fragmented vegetation type that occurs above 3200 m elevation on 14 scattered mountains and covers some 4525 km² in tropical Africa. Defined by the strong diurnal climate of “summer every day and winter every night,” the Afro-alpine Zone is typified by a unique flora characterized by Giant Groundsel and Giant Lobelia species. The Afro-alpine Zone is mostly concentrated in the eastern region of the continent, with a single western occurrence on Mount Cameroon. It is estimated that the Afro-alpine region harbors between 515 and 521 species of flowering plants, 52 fern species, and >277 moss species, with endemism levels around 35% for flowering plants and 30% for mosses. This represents moderate diversity and richness compared to other tropical alpine areas such as the Páramos of the South American Andes and the highlands of New Guinea. Typical plant communities in the Afro-alpine are tussock- and shrub-dominated grasslands and alpine bogs or fens, in which are embedded communities of Giant Lobelias and particularly Giant Groundsels. Biogeographically, the evolution of Afro-alpine diversity appears to be driven by age, size, and the geographical proximity of the mountains to each other, similar to the processes described by the General Dynamic Model for oceanic islands but overall much more complex. Due to the difficulty of exploration in some of these mountains and the limitation and biases of the available literature, there is work to be done in terms of finalizing data on the Afro-alpine biotic composition and determining its underlying biogeographic history. Understanding these processes may provide important insights on the conservation of these unique habitats, which are especially threatened by immediate human activities (e.g., overuse of fire) and anthropogenic-driven climatic change.

The Afro-Alpine Zone on Tropical African Mountains

Introduction

The unique vegetation found above the forests on the highest mountains of tropical Africa has held a strong fascination for botanists and plant geographers for over a century (Engler, 1892; Grimshaw, 2001; Eggermont et al., 2009). The focus of this attraction has been the unique diversity in this Afro-alpine Zone (Hedberg, 1957; White, 1983; Plate 1), the similarities in plant form and function to other tropical alpine regions of the world (e.g., the Páramo of the Andes; Hedberg, 1970, 1992; Sklenář et al., 2011; Anthelme et al., 2014), and the phytogeographical “conundrum” of how a similar Afro-alpine flora evolved on different host mountains, despite the occurrence of large distances of unsuitable habitats separating them (Hedberg, 1957; Gehrke and Linder, 2014; Chala et al., 2017, etc.). Modern methods in ecology and biogeography have largely resolved these questions (e.g., Gehrke and Linder, 2009; Linder, 2014; Gehrke et al., 2016; Kandziara et al., 2016; Chala et al., 2017). Nevertheless, the fascination of this unique habitat in Africa, its species composition, and its charismatic giant species (Kandziara et al., 2016), remains strong.

Alpine vegetation in tropical Africa—generally referred to as the tropical Afro-alpine Zone and defined by strong diurnal temperature variation, as opposed to seasonal climate variation (Hedberg, 1951; Hauman, 1955; White, 1983)—is confined to the highest mountains in eastern Africa: Mounts Elgon, Kenya, Kilimanjaro and Meru; the Aberdare, Ruwenzori, Simien and Bale mountains; and the Virunga volcanoes (Sklenář et al., 2011); and one in western Africa: Mount Cameroon (Gehrke and Linder, 2014; Fig. 1; Table 1; Plate 1). Gehrke and Linder (2014) include the Cherangani Hills and the Loolmalasin, Hanang, and Imatong mountains (eastern Africa) in their Afro-alpine circumscription—although these would be considered marginal by other authors (e.g., Hedberg, 1951). In addition, scattered tropical alpine elements (and more extensive sub-alpine vegetation) can be found as far south as South Africa and on Madagascar and Réunion Islands, but none of those can be considered true tropical alpine environments (Gehrke and Linder, 2014). Carbutt and Edwards (2015) have argued for a temperate Austro-alpine definition for the Maloti-Drakensberg (part of Linder’s, 2014 Austro-temperate flora, and separated from Killick’s, 1978 Afro-alpine definition), given that this alpine area is ecologically and physiognomically distinct from the tropical Afro-alpine, notably due to strong seasonal rather than diurnal temperature variation. Separation of the African tropical montane (i.e., Afromontane sensu White, 1983) and tropical alpine (i.e., tropical Afro-alpine sensu Hedberg, 1951) is also supported by multiple-genera phylogenetic reconstruction (Linder, 2014).

The Afro-alpine Zone represents the smallest and youngest phytogeographical region in Africa (Hedberg, 1951; Linder, 2014). As is the case in African mountain floristics and phytosociology, debate continues around this vegetation’s best circumscription in the Afromontane phytogeographical concept conceived by White (1978, 1983). Nonetheless, we consider it pragmatic to follow Hedberg’s (1951) definition of this Zone on the “roof of Africa.” In tropical African mountains, the concept of “Zone” and “vegetation type” is largely synonymous in that these free-standing mountains of high relative elevation allow for clear bands of vegetation that are more or less discrete from one another (although ecotonal transitions are always present; Hedberg, 1951; Bussmann, 2006). The generalized order of sequence of these Zones, from lowest to highest elevation, is: Lowland Rainforest, Montane Forest (including Bamboo Forest and Cloud Forest), Giant Heath Forest, Afro-alpine, and Nival (Hedberg, 1951; Niemelä and Pellikka, 2004; Bussmann, 2006; Fig. 2). Following Hedberg (1951), the Afro-alpine Zone is bounded by the Giant Heath Forest Zone below and the Nival Zone above, in an envelope of ca. 3200/3500–5000 m. Grimshaw (2001) argues for the inclusion of the Giant Heath Zone into the Afro-alpine Zone, but we confine ourselves to Hedberg’s (1951) more discrete definition that separates the two (although the lower elevation limit of Afro-alpine varies according to authors, e.g., Hedberg 3500 m; Gehrke and Linder 3200–3600/3800 m).

African mountain building resulting in elevations high enough to support alpine vegetation has been in progress since the Eocene (Fig. 3), mostly from repeated volcanic activity and uplift events associated with the East African Rift System and the

Plate 1 Tropical African alpine (Afro-alpine) landscapes. Cameroon volcanic line (Burke, 2001; Schlüter, 1997; Tsafack et al., 2009). The result is 14 scattered, high-elevation mountains in eastern Africa and one in western Africa that supports isolated Afro-alpine habitats, with these host mountains being 40 million years (the Bale and Simien Mountains) to less than one million years old (Mount Meru), or still volcanically active (Mount Cameroon) (Table 1). Of the 14 host mountains, only the Ethiopian Highlands (Bale and Simien mountains), Mount Elgon, and the Imatong date from late Eocene, with most of the other mountains (at least in terms of factors allowing them to reach current elevations) being younger (Schlüter, 1997; Gehrke and Linder, 2014).

From Hedberg's (1951) stricter definition of a lower limit of 3500 m to Gehrke and Linder's (2014) laxer lower limit of 3200 m, the scattered tropical Afro-alpine fragments together cover between 3500 and 4525 km². According to Gehrke and Linder (2014), the largest Afro-alpine areas occur in the Ethiopian Highlands (2200 km²), with the Bale Mountains hosting the largest single component (1200 km²); the Cherangani Hills, the Hanang, the Imatong, and the Loolmalasin mountains have the smallest area components, each less than five square kilometers (Gehrke and Linder, 2014; Table 1). It is interesting to note that there is only a weak correlation between Afro-alpine surface area and the summit elevation of the host mountains (Fig. 4). This is indicative that absolute elevation is not as important as the surface area present within the suitable climatic belt and suggests that the climatic envelope suitable for the Afro-alpine evolution has been increasing relative to the host mountain elevation since the Miocene.

Floristic Diversity

Data availability and constraints

Different elevational bounds, and therefore spatial delimitations of the Afro-alpine Zone by different authors have resulted in numerous different floristic statistics for Afro-alpine diversity (Gehrke and Linder, 2014). The most recent and comprehensive assessment of floristic diversity is Gehrke and Linder's (2014) work on flowering species diversity and distributions in the Afro-alpine Zone, and is the first such synthesis following Hedberg's (1957) much earlier work. On-going and unpublished work (e.g., Abdi, 2013; Wekesa, 2015) will require a further revision of Gehrke and Linder's (2014) work in future.

As with any spatially defined entity, "species accounting" is always in flux, with tallies changing as continued work in relatively poorly botanized areas are targeted for further exploration. Additionally, new records come to light, the taxonomies of species' complexes are untangled, and herbarium records become easier to access in a digitized world. Even Gehrke and Linder's (2014) work shows conflicting figures, and how they arrived at their figures (especially for endemic tallies) is not completely clear. Despite the above, we know more about plant diversity in the Afro-alpine than before, thanks largely to Gehrke and Linder (2014).

Although some non-Spermatophyte plants—like ferns, mosses and liverworts—and organisms like lichens are ecologically important components in the Afro-alpine (Pócs, 1991; Eggermont et al., 2009; Wekesa, 2015) and range in elevation into the Nival Zone, they did not form part of Gehrke and Linder's (2014) work, which focused on flowering plants. Gathering such non-Spermatophyte data for the Afro-alpine would require similar methods used by Gehrke and Linder (2014) for flowering plants, as most relevant data remain embedded in national and regional flora publications or incidental records. Although it primarily presents an interesting opportunity for future work, a brief window into this diversity is provided.

While Gehrke and Linder (2014) provide the most comprehensive figures for flowering plant diversity, Hemp (2002) provides the most comprehensive overview of available fern data. Although his data are confined to Mount Kilimanjaro and regional comparisons to past works, Hemp (2002) states that this mountain has the highest fern diversity in eastern Africa, and therefore gives us some indication of fern diversity in the Afro-alpine. Although most moss collecting on tropical African mountains has been in Montane Forests, Bizot et al. (1978), Pócs (1991), and Wekesa (2015) provide an insightful sample of moss diversity in the Afro-alpine. We have not considered liverworts and lesser-known lichens in this contribution, other than incidental notes, for instance from Pócs (1991).

Flowering plant diversity in the Afro-alpine

According to Gehrke and Linder (2014) the number of Afro-alpine flowering plant species, in its liberal sense (i.e., above 3200 m) is considered to be between 515 and 521 species (representing 50 families and 191 genera), versus 155 species (representing 29 families and 70 genera) in its stricter sense (i.e., above 3600 m) (Table 2). The best-represented families above 3200 m are Asteraceae (comprising 26% of the Afro-alpine flora), followed by Poaceae (11%), Fabaceae and Rosaceae (both 5%); above 3600 m this becomes Asteraceae (28%), Poaceae (21%), and Rosaceae (8.5%). The most species-rich genera (above both 3200 and 3600 m) are (in numerical order): *Senecio*, *Alchemilla*, *Dendrosenecio*, *Lobelia* and *Helichrysum* (Plates 2 and 3); *Festuca* and *Suertia* become more important proportionally in the flora above 3600 m. The highest elevation recorded for an Afro-alpine flowering species is *Helichrysum newii*, at 5670 m on Mount Kilimanjaro (Willis, 2000).

Gehrke and Linder (2014) determined four mountain clusters in the Afro-alpine based on floristic similarity (Table 2). The South-eastern East African Mountain Cluster (comprising Mounts Elgon, Kenya, Kilimanjaro, Meru, the Cherangani Hills, Hanang,

Fig. 2 Schematic of the Vegetation Zones in tropical African mountains. Based on Bussmann, R. W. (2006). Vegetation zonation and nomenclature of African mountains—an overview. *Lyonia* 11, 41–66.

Loolmalasin and the Aberdares) has the highest species diversity, harboring 363 species. The West African Mountain Cluster (comprising Mount Cameroon) has the lowest species diversity, with 51 species. The Western East African Mountain Cluster (comprising the Virungas and Ruwenzoris) has 339 species, and the Northern East African Mountain Cluster (comprising the Imatong and the Ethiopian highlands) has 306 species. Floristically, the West African Mountain Cluster is sufficiently distinct from the remainder of the Afro-alpine to be considered its own sub-region within the Afro-alpine (Gehrke and Linder, 2014, confirming Smith and Cleef, 1988). Hedberg (1964) suggested that the Ethiopian component (most of Gehrke and Linder's, 2014 Northern East African Mountain Cluster) should be its own subgroup due to the absence of *Dendrosenecio* and most shrubby *Alchemilla*, and the unique presence of *Primula* and *Rosa*, although these differences are not enough to statistically alter Gehrke and Linder's (2014) analysis (further fieldwork, aligned with phylogenetically weighted approaches and standardized field methods in the generally poorly explored Ethiopian Highlands, may change this however).

Of the individual mountain ranges, the Bale Mountains (in south-eastern Ethiopia) have the highest Afro-alpine species diversity (at 274 species; Fig. 5; Table 2), while Loolmalasin has the lowest (at 30 species). Other high diversity highlands are Mounts Elgon (273 species) and Kenya (269 species), the Aberdares (262 species), the Simien Mountains (238 species), and Mount Kilimanjaro (227 species). It is surprising that the Ruwenzoris score much lower (at 167 species) than the Virungas (with 180 species), and that Mount Meru (116 species) has substantially fewer species (111 fewer species) than its larger neighbor, Mount Kilimanjaro. Unsurprisingly, therefore, species diversity is proportional to Afro-alpine area (Fig. 6). In contrast, small mountains may host notable species richness. For example the Virungas harbor 180 species despite having only a 20 km² alpine area, while the neighboring, much larger (500 km²) Ruwenzoris are home to only 167 species. Mount Elgon, despite having only 450 km² of Afro-alpine area, has the second highest species richness (273 species)—a level of richness comparable to that of the massive 1200 km² alpine area of Bale (274 species).

Fern diversity in the Afro-alpine

Although Africa is relatively fern species-poor, the Afromontane region sensu White (1978) is one of the richer fern enclaves on the continent (Liu et al., 2016). In this Afromontane sensu lato, fern diversity is highest within the Montane Forest Zone (Hemp, 2002), although those occurring in the Afro-alpine perhaps show more interesting macro-scale distribution patterns with associated biogeographical interest (Aldasoro et al., 2004). Ferns are recognized as having varying elevation distributions on different mountains in tropical Africa, and species elevation limits vary from one mountain to another (Hemp, 2002), making it more challenging to define a particular Afro-alpine fern flora. Sampling deficiency is almost certainly a strong factor, with records (distribution and elevational) currently being ad hoc rather than representing a reliable elevation continuum across the Afro-alpine (only Wekesa, 2015 did this, for Mount Kenya). Nevertheless, the fern flora of the Afro-alpine is biogeographically

Fig. 4 The relationship between surface area and summit elevation in the Afro-alpine Zone of tropical Africa.

Table 2 Patterns of flowering plant species diversity and endemism in the Afro-alpine Zone of tropical African mountains

Site	Plant diversity	Endemics
Afro-alpine sensu lato (>3200 m)	515–521 (av. of 518 = 100%)	168–184 (32–36)
Afro-alpine sensu stricto (>3600 m)	155 (30)	155 (30)
Northern East African Mountain Cluster	306 (59)	85–90 (16–17)
Bale	274 (53)	6–11 (1–2)
Simien	238 (46)	22–24 (4–5)
Imatong	65 (13)	0 (0)
South-eastern East African Mountain Cluster	363 (70)	54–97 (10–19)
Mount Elgon	273 (53)	15–17 (3)
Mount Kenya	269 (52)	6–8 (1–2)
Aberdares	262 (51)	7 (1)
Mount Kilimanjaro	227 (53)	7 (1)
Mount Meru	116 (22)	0 (0)
Cherangani Hills	87 (17)	1 (0)
Hanang	63 (12)	0 (0)
Loolmalasin	30 (6)	0 (0)
Western East African Mountain Cluster	339 (65)	31–54 (6–10)
Virungas	180 (35)	8–9 (2)
Ruwenzoris	167 (32)	10–11 (2)
West African Mountain Cluster (=Mount Cameroon)	51 (10)	0–1 (0)

Given the conflicting data available for Endemics, both lower and upper figures available are provided. For both Plant Diversity and Endemism, percentage of the Afro-alpine flora (i.e., occurring >3200 m) is indicated in parentheses.

Adapted from Gehrke, B. and Linder, H. P. (2014). Species richness, endemism and species composition in the tropical Afroalpine flora. *Alpine Botany* **124**, 165–177.

fascinating, having strong links to the temperate montane grasslands of southern Africa (as many as 70% shared species) and the sub-Antarctic islands (Jacobsen and Jacobsen, 1989; Aldasoro et al., 2004).

Hemp (2002) provided the most data for considering an Afro-alpine fern flora, based on extensive work on Mount Kilimanjaro and comparisons with previous work in the region by Pichi Sermolli (1983, 1985), Johns (1991) and Faden (1994). Accordingly, it appears that there are at least 52 Afro-alpine fern species (34 from 3200 m upwards, dropping to only 18 species above 3600 m). The robustness of Hemp's (2002) work is evident when compared Jacobsen and Jacobsen (1989), who only record 26 species above 3200 m and eight species above 3600 m (from the Kenyan highlands and Albertine rift mountains). The record for the highest elevation fern is *Cystopteris fragilis* at 4750 m (Willis, 2000), followed by *Huperzia saururus* at 4575 m (Jacobsen and Jacobsen, 1989).

Moss diversity in the Afro-alpine

According to Geffert et al. (2013), the eastern African mountains are a global center of moss diversity, mirroring a global trend wherein mountains play a much more important role in driving moss diversity and endemism than does latitude. Spence and Pócs (1989) recorded 277 moss species from the Afro-alpine in eastern Africa. From Bizot et al. (1978), some 72 species are present at or above 4000 m, with *Andreaea mildbraedii* reaching 5000 m (Bizot et al., 1978) and *Schistidium apocarpum* reaching 5050 m (Spence and Pócs, 1989). On Mount Kenya the mosses *Grimmia* (forming "moss balls"; Hedberg, 1964; Pócs, 1991) and *Andreaea* occur at

Plate 2 Characteristic genera of the Afro-alpine include *Senecio* and *Euryops* (both Asteraceae), *Alchemilla* (Rosaceae) and *Swertia* (Gentianaceae). (A) *Senecio purpureus*, a wide-spread species in the Afro-alpine and temperate Afro-austral grasslands—here on Mount Cameroon (Cameroon), c.3800 m; (B) *Euryops brownei*, endemic to the Aberdares, Cherangani Hills and Mounts Elgon, Kenya and Meru—here on Mount Elgon (Uganda), c.3800 m; (C) *Alchemilla argyrophylla*, a widespread species in the Afro-alpine, here on Mount Elgon (Uganda), c.4000 m; (D) *Swertia subnivalis*, Mount Elgon (Uganda), c.3800 m. Photographs: Berit Gehrke (A), Ralph Clark (B–D).

higher elevations (4600–4800 m) than any of the vascular plants on that mountain (Wekesa, 2015). Pócs (1991) indicates that *Dendrosenecio* communities, alpine tussock grassland/shrub land and rocky cliffs are the most important Afro-alpine habitats for mosses (as well as for liverworts and lichens). Willis (2000), for example, noted that 40 moss species could occur on one *Dendrosenecio* plant in Mount Kilimanjaro's Afro-alpine Zone. As is the case for ferns, moss species distributions show intriguing connections to the temperate mountains of southern Africa, the southern hemisphere in general (e.g., *Bryum laevigatum*), and the sub-Antarctic (Bizot et al., 1978; Pócs, 2004). Within the Afro-alpine Zone, the floristic relationship between the moss flora of Mounts Kilimanjaro and Kenya is stronger than between any other mountains (Pócs, 1991).

Comments on liverwort and lichen diversity in the Afro-alpine

According to Pócs (1991), at least 25 liverwort species occur on Mount Kilimanjaro's Afro-alpine Zone above 3200 m, 19 of which extend above 3600 m; *Marsupella africana* reaches 4200 m (Pócs, 1991). Eggermont et al. (2009) indicate that *Umbilicaria* and *Usnea* lichens dominate in the Nival Zone of the Ruwenzoris, and Pócs (1991) recorded *Omphalodina melanophthalma* and *Umbilicaria aprina* at 5400 m on Mount Kilimanjaro. Just as with flowering plants, distribution patterns of Afro-alpine ferns and mosses, liverworts and lichens have complex and interesting biogeographical relationships within the Afro-alpine and beyond, notably with the high Asian mountains (Pócs, 1991).

Plate 3 Everlastings (*Helichrysum*, Asteraceae) are typical of the Afro-alpine Zone. (A) *Helichrysum stuhlmannii*, widespread in the Afro-alpine, here on the Bale Mountains (Ethiopia); (B) *Helichrysum* sp., in bud on Mount Cameroon (Cameroon), c.3600 m; (C) *Helichrysum* cf. *formosissimum*, in flower on Mount Elgon (Uganda), c.3800 m; (D) *Helichrysum* cf. *meyer-johannis*, Mount Elgon (Uganda), c.3800 m; (E) Alpine grassland dominated by *Helichrysum stuhlmannii*, Mount Elgon (Uganda), c.3800 m. Photographs: Peter Linder (A), Berit Gehrke (B), Ralph Clark (C–E).

Endemism

Data sources and constraints

As for flowering plant diversity, Gehrke and Linder (2014) provide the most recent synthesis of flowering plant endemism in the Afro-alpine. Unfortunately however, this work provides confusing results that are difficult to interpret in relation to elevation (above 3200/3600 m), as is their grouping of four mountain clusters, versus consideration of individual mountains (e.g. their “single mountain endemics” concept). There are also discrepancies between the figures in the tables, text and supplementary material that make firm endemism figures difficult to discern.

Although Aldasoro et al. (2004) indicates that the mountains of eastern and western Africa host significant fern endemism, actual data on Afro-alpine fern endemism was difficult to source. As for diversity, it may be that a careful mining of regional literature will yield accurate estimates of levels of Afro-alpine fern endemism and associated patterns; as a result we have excluded ferns from this component. Pócs (1991) provided the most detail on probable moss endemism for the Afro-alpine, although these

Fig. 5 Plant species richness and endemism as distributed in the Afro-alpine Zone of tropical Africa.

Fig. 6 Species-area curve for Afro-alpine plant richness in the tropical African mountains.

data are still scanty. As for ferns, data on lichen endemism is unavailable at present without a dedicated data gathering process, and lichens are therefore also excluded.

Flowering plants

Gehrke and Linder (2014) indicated that 168–184 flowering plant species could be considered Afro-alpine endemics (i.e., presumably confined to regions above 3200 m), comprising 32%–36% of the Afro-alpine flowering plant flora above 3200 m (Table 2). This compares to Hedberg’s (1951, 1969) stricter lower limit of 3500 m and associated 81% endemism.

Because of the ambiguous results in Gehrke and Linder (2014), it is not possible to state with confidence the patterns of endemism in terms of their four mountain clusters (Table 2). If we take their highest figures, the *South-eastern East African Mountain*

Cluster has the highest recorded endemism (97), and the *Western African Mountain Cluster* the lowest (one); the *Northern East African Mountain Cluster* (90) is a close second, followed by the *Western East African Mountain Cluster* (54). However, if we take their lower limits, the *Northern East African Mountain Cluster* has the highest level of endemism (85), followed by the *South-eastern East African Mountain Cluster* (54). Of the individual mountain ranges, the Simien has the highest number of local endemics (22–24), and Mount Meru, Hanang, and Loolmalasin the least, with no Afro-alpine endemics on any of them. Mount Elgon, the Ruwenzoris and Bale Mountains follow the Simien Mountains in local endemism, with 15–17, 10–11 and 6–11 endemic species each. All other mountains host endemics in single figures, that is, the Virungas (eight to nine), the Aberdares and Mount Kilimanjaro (seven each), Mount Kenya (six to eight), and the Cherangani Hills and Mount Cameroon (one each). If we consider the extent of the Afro-alpine Zone on each mountain, and therefore highest level of endemic richness per unit area, the Virungas—despite having only 20 km² of alpine area—are the richest in endemic species (eight to nine endemic species), richer than host mountains with much larger Afro-alpine areas, like Mount Kenya and Mount Kilimanjaro (Fig. 7).

Mount Cameroon (i.e., the *West African Mountain Cluster*) is worth a special mention. Based on their liberal and strict delimitations of 3200 m and 3600 m, Gehrke and Linder (2014) considered there to be only one Afro-alpine endemic on Mount Cameroon, although this solitary shield volcano seems to host up to 19 moorland and grassland–forest interface endemics (Maitland, 1932; Cheek et al., 1996; Linder et al., 2010). As this grassland extends down to ca. 2600 m, most of the grassland endemics fall outside Gehrke and Linder's (2014) definitions of "Afro-alpine endemic" (liberal or strict). However, based on Maitland's (1932) descriptions of alpine communities and more recent work by Cheek et al. (1996), two species (*Helichrysum mannii* and *Pentameris pictigluma* var. *mannii*) would qualify as true Afro-alpine endemics from Mount Cameroon, apparently being confined to elevations above 3600 m. Smith and Cleef (1988), for example used 2985 m as the lower limit for data from Mount Cameroon for their global tropical alpine analysis. Mount Meru also deserves mention in that—although Gehrke and Linder (2014) consider it to have no Afro-alpine endemics—Afro-alpine-associated endemics certainly occur there (Knox, 2005).

Some notable Afro-alpine endemics among the flowering plants are the Giant Lobelias *Lobelia* species and Giant Groundsels *Dendrosenecio* species (Mabberley, 1974, 1975; Givnish, 2010; Plates 4–7). These giant forms have attracted much research attention from physiognomic, ecological, taxonomic, and phylogeographical perspectives (Hedberg, 1969; Zhao et al., 2016, etc.). The taxonomies of these two genera are particularly complex, and have motivated a reasonable debate as to species delimitations (Knox and Palmer, 1995, 1998) and therefore endemism tallies. While *Dendrosenecio* is absent from Mount Cameroon, *Lobelia* (*L. columnaris*) is present, representing a ubiquitous "giant genus" in the entire Afro-alpine. Currently, 11 species (and 11 subspecies!) of *Dendrosenecio* are recognized (Table 3). Only three of these species can be said to be true Afro-alpine endemics (as per Gehrke and Linder's, 2014 definition). Eight species are considered near-endemics, with none exclusively below the Afro-alpine Zone. For the 12 species of Giant *Lobelia* currently recognized (Table 4), only two are true Afro-alpine endemics, six are near-endemics, and the remaining four do not extend above the Montane or Giant Heath Zones into the Afro-alpine Zone. Gehrke and Linder (2014) note another four *Lobelia* species that occur in the Afro-alpine Zone that are not giant species.

Mosses and liverwort endemism in the Afro-alpine

Pócs (1991) indicated that there are 83 species of moss endemic to the Afro-alpine. Endemism is evident on single mountains, such as the 12 mosses and liverworts endemic to Mount Kilimanjaro, eight of which occur in the Afro-alpine Zone and nine extend into the Nival Zone (Pócs, 1991). According to Pócs (1991), there are at least 20 species of liverwort endemic to the Afro-alpine Zone.

Fig. 7 Species-area curve for Afro-alpine endemics in the tropical African mountains. Data from Gehrke, B. and Linder, H. P. (2014). Species richness, endemism and species composition in the tropical Afroalpine flora. *Alpine Botany* 124, 165–177.

Plate 4 Giant forms of *Lobelia* (Campanulaceae) are typical in tropical African mountains, as they are in other tropical areas such as Oceania, with only a few occurring in the Afro-alpine in tropical Africa. (A) *L. columnaris*, a forest species endemic to Mount Cameroon and the Bamenda Highlands (Cameroon, Nigeria); (B) *L. giberroa*, a common and widespread eastern Afromontane forest species; (C) *L. stuhlmannii*, in the Ruwenzoris (Uganda); (D) *L. aberdarica*, endemic to Mount Elgon, the Aberdares and Cherangani Hills (Kenya, Uganda), here on Mount Elgon at c.3200 m; (E) *L. wolastonii*, a colony in the Ruwenzoris (Uganda). Photographs: Berit Gehrke (A), Peter Linder (B, C, E), Ralph Clark (D).

Characteristic Species and Communities

There are very distinct plant communities within the Afro-alpine Zone (Hedberg, 1964; Niemelä and Pellikka, 2004) and several primary plant communities can be recognized, notably extensive tussock- and shrub-dominated grasslands and alpine bogs or fens (Rejmankova and Rejmanek, 1995; Willis, 2000; Niemelä and Pellikka, 2004). The areal extent, structure, and species composition of these communities varies from mountain to mountain. There is, for instance, much more alpine bog on the Ruwenzoris than on the mountains east of the Rift Valley (Rejmankova and Rejmanek, 1995). Sparse to dense communities of Giant Groundsel and Giant *Lobelia* occur in both tussock grassland/shrub land and alpine bogs.

Tussock grasslands are dominated by tufted grasses of the genera *Agrostis*, *Andropogon*, *Descampsia*, *Festuca*, *Koeleria*, *Pentameris*, and *Poa*. Shrubs are represented particularly by *Alchemilla* and *Helichrysum* (Plates 1–3), with notable others including *Euryops* and *Erica* (Plates 2 and 8). Such grassland and shrub-land is relatively rich in both diversity and Afro-alpine endemic species, with

Plate 5 Giant Lobelia (cont.). interesting biogeographical connections, such as with the “Cape Flora” of far southern South Africa (Weimarck, 1941; Hedberg, 1970, 1986; Linder, 2014). The most characteristic genera in alpine bogs are *Carex* sedges; mosses such as *Meesia*, *Scapania*, *Sematophyllum*, and *Sphagnum* (Rejmankova and Rejmanek, 1995); various *Luzula*, *Ranunculus*, and—prominently—*Lobelia* and *Dendrosenecio* (Pócs, 1991; Plates 4–7).

Drivers of Plant Diversity and Endemism in the Afro-Alpine

Hedberg (1969, 1970, 1986) compared the widely scattered Afro-alpine Zone components to the extreme isolation experienced by many oceanic islands. In fact, he considered this level of isolation to be even stronger than that experienced on oceanic islands, due to the absence of ocean currents that would transport propagules (Hedberg, 1969, 1970). We know, however, that many agents of dispersal must have operated in creating this unique flora on the roof of Africa (Hedberg, 1970; Chala et al., 2017). This is born out by the array of genetic relationships the Afro-alpine flora shares with most of the world (Gehrke and Linder, 2009; Gehrke and Linder, 2014; Chala et al., 2017). The idea of the Afro-alpine Zone comprising the ultimate “sky islands” and, therefore, amenable to test hypothesis in terms of the General Dynamic Model of Whittaker et al. (2008), has been most comprehensively attempted by

Plate 6 The Giant Groundsels comprise the genus *Dendrosenecio* (Asteraceae), endemic to the tropical African mountains, with most species occurring in the Giant Heath and Afro-alpine Zones. (A) *D. elgonensis*, endemic to Mount Elgon (Uganda), 3000–4300 m; (B) *D. adnivalis*, endemic to the Ruwenzoris and Virungas (Uganda, Rwanda, Burundi and the Democratic Republic of the Congo); (C) *D. kilimanjari*, endemic to Mount Kilimanjaro (Tanzania); (D) *D. keniensis*, endemic to Mount Kenya (Kenya); (E) Old *D. adnivalis* community, in the Ruwenzoris. Photographs: Ralph Clark (A), Christopher Gardner (B), Nigel Forshaw (C), Tara Hetz (D), Peter Linder (E).

Gehrke and Linder (2014). This—and subsequent work (e.g., Kandziora et al., 2016; Zhao et al., 2016; Chala et al., 2017, etc.) has shown that there is surprising connectivity between individual Afro-alpine communities, as indicated by the evidence of shared species and complex phylogeographic patterns. This, in turn, suggests multiple dispersal and colonization events.

Plant diversity and endemism in the Afro-alpine Zone appears to be driven primarily by age, size, and geographical proximity of the host mountains to one another (Gehrke and Linder, 2014). The ages of the host mountains appear to be the most important factor in determining plant richness and diversity, as older mountains have had more time to accumulate diversity, both through colonization and in situ speciation (Gehrke and Linder, 2014). Converse to this, mountains that are senescent are often more eroded, and may have thus lost many Afro-alpine elements through loss of elevation and loss of topographic complexity (sensu

Plate 7 Giant Groundsels (cont.). Photographs: Mike Loomis (A), Tara Hetz (B), Christopher Gardner (C and D).

Whittaker et al., 2008 for mature oceanic islands). An example is the Cherangani Hills, and to some extent the Aberdares (Gehrke and Linder, 2014), which only just retain some Afro-alpine elements. Isolation is a strong driver of higher endemism but generally favors lower species diversity (Chala et al., 2017). However, the most isolated Afro-alpine area (Mount Cameroon) does not show either high levels of diversity or endemism, as a result of the recent age of the higher elevations of the mountain. Here there are still periodic volcanic eruptions that cause local extinctions (Cheek et al., 1996; Gehrke and Linder, 2014).

While in broad terms the age, size, and proximity of mountains hosting Afro-alpine vegetation might have the most explanatory power (Gehrke and Linder, 2014), intra-specific patterns of genetic structuring suggest that much more dynamic biogeographical histories led to the creation of these Afro-alpine communities (Chala et al., 2017). Ruggedness most certainly plays a role in enhancing fine-scale habitat heterogeneity (Whittaker et al., 2008), which has been suggested as an important feature determining

Table 3 Summary of Giant Groundsel (*Dendrosenecio*) in the Afro-alpine Zone

species richness in Afro-alpine environments (Gehrke and Linder, 2014)—especially in non-Spermatophytes. Geological stability of the host mountain is also an important factor, for instance long time periods of dormancy on volcanic mountains are required for colonization and speciation. Following the General Dynamic Model, it is expected that intermediate-aged landscapes present higher terrain ruggedness than either much younger or much older ones. In Afro-alpine environments, however, older (Bale and Simien), intermediate (Mount Elgon), and recently (Mount Kenya, Aberdares, and Mount Kilimanjaro) formed mountains present similar species richness. Factors such as elevational descent of vegetation zones during cooler periods (e.g., the Last Glacial Maximum), repeat dispersal and colonization events for the same species, the historical presence of grassland corridors, and unexpected evidence of an ability of Afro-alpine species to cross seemingly permanent barriers (such as the Turkana lowlands), all point to an intriguing and complex biogeographical history (Masao et al., 2013; Wondimu et al., 2014; Chala et al., 2017). This suggests that

Plate 8 Heaths or Heathers (*Erica*, Ericaceae) is a typical Afro-alpine genus with links to both the “Cape” flora of southern Africa and the temperate flora of Europe. (A) *Erica silvatica*, Mount Cameroon (Cameroon), c.3600 m; (B) *Erica silvatica*, Mount Elgon (Uganda), c.3800 m; (C) *Erica mannii* subsp. *mannii*, Mount Cameroon (Cameroon), c.3600 m. Photographs: Berit Gehrke (A and C), Ralph Clark (B).

the historical biogeography of the tropical alpine in Africa is more complex than a simple application of the General Dynamic Model.

Global Comparisons

When compared in a species-area relationship to other tropical alpine regions in the world (i.e., the Páramo, the highlands of New Guinea, and Oceania; Gehrke and Linder, 2014; Costin et al., 1979; Pickering et al., 2008; Sklenář et al., 2011; Royen, 1979; Fig. 8), the Afro-alpine Zone is relatively species-poor (for flowering plants) and the Páramo is the most species diverse (Smith and Cleef, 1988; Sklenář et al., 2011). Gehrke and Linder (2014) note that even when accounting for area (i.e., richness) the Afro-alpine is still species-poor (Smith and Cleef, 1988). However, the lack of detailed data for some mountains may skew this, and intensive botanical collecting efforts in the more poorly documented Afro-alpine areas may increase both the overall species tally as well as that of level of endemism (although this would require an intensive effort). Interestingly, although gymnosperms are locally dominant in Afromontane forests (i.e., *Podocarpus*), they do not occur in the Afro-alpine. However, they are present in southeastern Asian tropical alpine habitats (Smith and Cleef, 1988).

Fig. 8 Species-area curve for four tropical alpine areas globally.

Much has been made of the convergent evolution in the giant growth forms in the Afro-alpine (Giant Groundsel and Giant Lobelia), Páramo (Frailejones *Espeletia*), and vegetation of high elevations in the Hawai'i archipelago (Silverswords *Argyroxiphium* and *Lobelia* sect. *Galeatella*), with remarkably similar forms in unrelated groups present in the tropical alpine (Hedberg and Hedberg, 1979; Antonelli, 2009; Givnish, 2010). Unlike the other tropical alpine giant groups globally, Giant Lobelias are not confined to the tropical alpine and also occur at lower elevations on the same mountains as their alpine relatives (Givnish, 2010).

Future Research Needs

The Delimitation Problem

The traditional delimitation around defining the Afro-alpine based on elevation, while pragmatic in many ways, needs to be reassessed. Both Mounts Cameroon and Meru show a pattern in which grassland (potentially Afro-alpine) occurs below 3200 m, hosting numerous typically Afro-alpine-like endemics (e.g., *Dendrosenecio meruensis*) that scarcely occur in the Giant Heath or Montane Forest Zones. It is worth noting that Smith and Cleef (1988) used different lower elevations for different mountains in their global comparison of tropical alpine floras, and Gehrke and Linder (2014) attempted to accommodate the effect of latitude on vegetation zones in their synopsis. Also, Hedberg (1970) indicated that many typical Afro-alpine-associated species occur well below the Afro-alpine lower limit, some as low as 1000 m. Admittedly, the situation becomes more confusing when large-scale transformation of Giant Heathland (e.g., from over-use of fire; Wesche et al., 2000; Hemp, 2005), artificially transforms such woody habitats into alpine-like environments (Friis and Demissew, 2001). Nevertheless, a climatic-based spatial delimitation of the Afro-alpine may be more practical than just an elevational one, as the relative elevation, overall bulk, ruggedness and resulting local climate of each mountain/mountain block may result in Afro-alpine vegetation being favored at different elevations on individual mountains.

The Holdridge life zone system (where "alpine" is defined as the mean bio-temperature being between 1.5°C and 3°C; Holdridge, 1947), or Köppen climate classification (where the Alpine Zone is defined as no month in the year having a mean temperature above 10°C), may be more appropriate in defining the Afro-alpine Zone. The Holdridge system is considered to be better suited to tropical vegetation and does not consider elevation as a primary factor. While mostly applied in the deciduous fruit and nut industry (Luedeling and Brown, 2011; Luedeling, 2012), the positive chill unit (PCU) concept (Linville, 1990; Schulze and Maharaj, 2007) could be explored as a method for defining strictly Afro-alpine endemics, based on accumulated 24 h minimum temperatures essential for survival and or reproduction of such species. There does not appear to be any literature on using the PCU concept in the tropical alpine (although it has been proposed for the Austro-alpine in southern Africa; van Wyk and Smith, 2001). In addition, the PCU concept may be a useful empirical measure of how individual Afro-alpine endemics might be (or are already being) affected by climate change, and what the actual temperature thresholds for functional extinction are.

The Continued Need for Comprehensive Fieldwork, Data Inventory, and Taxonomic Investigation

Grimshaw (2001, p. 954) noted that the Afro-alpine flora—despite a century of investigation—is still a flora "worthy of any research effort." Despite the small areal extent of the Afro-alpine, its high elevation, fragmented distribution, and rugged topography render it relatively difficult to thoroughly explore. Ethiopia, in particular, still requires extensive fieldwork to accurately determine the floristic composition of its Afro-alpine fragments (Puff and Nemomissa, 2005), notably in the Amba Alagi, Mount Gurage, Welel, Choqa, and Guna areas (Gehrke and Linder, 2014). Better-sampled mountains are also not exempt, including (somewhat

surprisingly) the charismatic Ruwenzoris, along with the Virungas and Mount Meru (Gehrke and Linder, 2014)—the latter a “stone’s throw” from the very intensely studied Mount Kilimanjaro. Some plant groups are particularly poorly documented, notably non-Spermatophytes (e.g., Wekesa, 2015). Focused collecting of such groups will no doubt greatly improve our diversity and biogeographical knowledge of these species in the Afro-alpine (and Nival Zone). In particular, the ecosystems services value of mosses and liverworts in the Afro-alpine (Pócs, 1991) makes them very important for further distributional, taxonomic, and ecological study. Geffert et al. (2013) indicated that although the eastern African mountains are a center of species richness and diversity globally for mosses, inventories and taxonomic revisions for such tropical areas are far from complete (compared to e.g., Europe). Pócs (1991) also affirmed that the lichen knowledge of the Afro-alpine is still poor.

Despite the overall low species diversity of the Afro-alpine, the taxonomy of many species and species complexes remains unresolved (Wondimu et al., 2017). Consequently, Wondimu et al. (2017) strongly urge continued field-work in the Afro-alpine to target localized populations representing the array of complex taxa in particular genera. Such collecting and resulting analyses (morphological, phylogenetic, etc.) will assist in delimiting species circumscriptions more clearly and further refine our understanding of the biogeographical history of the Afro-alpine. Revised taxonomic circumscriptions may also result in more robust diversity and endemism tallies.

Climate Change and Conservation

A large appeal of the Afro-alpine is the charismatic giant growth forms present, notably of *Lobelia* and *Dendrosenecio*. Using the Ethiopian Afro-alpine endemic *Lobelia rhynchopetalum* as a model, Chala et al. (2016) indicate that drastic habitat envelope contraction for Afro-alpine species is likely to occur with global warming. The implication is that Afro-alpine endemics may become very restricted in an already confined environment, with some species—especially those most obvious flagship giants adapted to the diurnal freeze-thaw cycle—being most at extinction risk (Chala et al., 2016). Long-term monitoring sites in the Afro-alpine and Nival Zones may be able to track the change of vegetation in response to climate change.

Immediate anthropogenic impacts usually outpace the impacts from climate change, and are often more of an immediate concern in terms of African mountains. *Dendrosenecio* plants, for instance, are vulnerable to frequent grass fires caused by hikers and honey gatherers (Niemelä and Pellikka, 2004).

Abstract

Southern Africa is characterized by a rich diversity of plant species and habitats with high levels of endemism. This region comprises nine biomes with a large number of vegetation types. One of these vegetation types is located on the high-lying mountains of the Drakensberg and is classified as being sub-Alpine vegetation. This sensitive ecosystem is described as a center of endemism and consists of unique plant species adapted to the relatively harsh environments.

Introduction

Alpine vegetation is found throughout the world on higher-lying mountains normally above 3000 m.a.s.l. Alpine vegetation grows in relatively harsh environmental conditions with extreme temperature and rainfall variations. The vegetation is characterized by the dominance of short grasses with meadows. Typical alpine vegetation is associated with the Alps in Europe, Andes in South America, Himalayas in South-east Asia, the Rockies in North America and the vegetation on the highest mountains of tropical East Africa (Aberdare Mountain, Mt. Ruwenzori, the Virunga Volcanos, Mt. Elgon, Mt. Kenia, Mt. Meru and Kilimanjaro).

Unlike the Andes and Rocky mountain ranges, most of the high- elevation African mountains occur as discrete island-like archipelagos. The continuum between the East African cluster and the Chimanimani Mountains in Zimbabwe is separated by the broad Zambezi valley, while the latter is separated from the South African cluster by the Limpopo valley (Fig. 1).

According to Van As et al. (2012) the vegetation of the slopes of high African mountains can be zoned into various elevational belts. The upper most belt (> 3600 m), which is absent in southern Africa, is dominated by Afroalpine vegetation comprising bryophytes, tussock grasses, giant lobelias (*Lobelia* spp.) and senecios (*Dendrosenecio* spp.). A sub-Alpine belt (between 2800 and 3600 m) is characterized by the dominance of various species of sclerophyllous genera such as *Erica*, *Philippia*, *Cliffortia* and *Passerina*. Lower down an undifferentiated Afromontane vegetation belt (1800–2800 m) occurs which consists of indigenous forests, shrublands, moist grasslands and wetlands. Although the vegetation of the East African mountains shows affinity with that of the higher mountains of southern Africa, there are also various differences in terms of species composition. According to White (1983) this affinity can be ascribed to the fact that where latitude compensates for elevation, as in the case of southern Africa, vegetation zones with Afromontane affinities occur at lower elevations.

The highest mountains in southern Africa span the western boundary of the KwaZulu-Natal Province to the southern high plateau of Lesotho and are known as the Maluti-Drakensberg range. This area is also described as the Drakensberg Alpine Center (DAC) of endemism (Van Wyk and Smith, 2001). The area is approximately 40,000 km² and occurs mostly above 1800 m above sea level. The Drakensberg Mountain range of South Africa is regarded as the southernmost point of the Afromontane region with alpine -like vegetation (Killick, 1997). The elevations of the highest peaks range between 2500 and 3480 m above sea level.

Geologically these mountains consist of basaltic rocks that were deposited over softer sandstone and shale layers, due to thick lava flows. The magma or molten rock flowed onto the area through a complex system of cracks or fissures, creating these mountains. Volcanic basalts are estimated to be up to 1.5 km thick (McCarthy and Rubidge, 2005). The chemical composition of the basalt is not homogeneous, resulting in some areas being less resistant to weathering. Thus, the opportunity for erosion was greater in certain sections than others. Whereas the basalts of the cap layers were brittle, underground crystallization of the lavas in cracks and fissures resulted in the formation of hard blue dolerite dykes and sills (Fig. 2).

Typical Plant Species of the Southern African Vegetation Belts

The vegetation of these areas consists of herbaceous vegetation that is dominated by mostly short grasses and forbs. Due to the cold temperatures, woody plants are normally absent. Where they are present, they are mostly scandent (short growth form with a spreading nature) or medium-sized shrubs in ravines or more protected rocky areas. In some ravines tall Afromontane forests are present (Fig. 3). The vegetation is divided into two groups:

Afromontane Vegetation Belt (1800–2800 m)

This belt includes three main vegetation types, namely Forests (restricted to sheltered ravines), open and closed shrublands, moist grasslands and wetlands. The following genera are typical for the forests: *Podocarpus*, *Curtisae*, *Rapanea*, *Chionanthus*, *Ocotea*, *Pittosporum*, *Ptaeroxylon*, *Prunus*, *Ilex*, *Halleria*, *Maytenus*, *Apodytes*, *Kiggelaria*, *Nuxia*, *Scolopia* and *Xymalos*. In the shrublands *Halleria*, *Buddleja*, *Leucosidea*, *Protea*, *Metalasia*, *Cliffortia*, *Metalasia*, *Greyia*, *Kiggelaria*, *Ilex*, *Muraltia*, *Erioccephalus*, and *Helichrysum* are typical genera present. Common genera for the shrublands, moist grassland and wetlands include *Protea*, *Leucosidea*, *Cussonia*, *Buddleja*, *Themeda*, *Rendlia*, *Phragmites*, *Festuca*, *Andropogon*, *Agrostis*, *Gunnera*, *Ficinia*, *Rumex*, *Ranunculus*, *Lobelia*, *Centella* and *Juncus*.

Sub-Alpine Belt (2800–3600 m)

The vegetation of these areas occurs on steep slopes and rolling plateaus and is characterized by treeless alpine vegetation consisting of grasses, scandent shrubs and herbaceous plants (Fig. 4). These areas include peaks such as Cathedral Peak, the inner and outer Horns and the Pyramid (Killick, 2012). Two main vegetation types can be distinguished, namely upland vegetation and peatlands/mires. The upland vegetation consists of species belonging to the following genera: *Passerina*, *Cliffortia*, *Erica*, *Philippia*, *Merxmuellera*, *Festuca*, *Koeleria*, *Bromus*, *Brachiaria*, *Festuca*, *Catalepis*, *Pentaschistis*, *Helichrysum*, *Ursinia*, *Lotononis*, *Crassula*, *Monsonia*, *Xerophyta*, *Psammotropha*, *Eumorphia*, *Pentameris*, *Thesium*. On the steep slopes the grasslands dominate, while the dwarf shrubs are more prominent on the crests and high plateau areas. The peatlands/mires include hydrophilic species belonging to the genera *Haplocarpa*, *Andropogon*, *Cotula*, *Isolepis*, *Ranunculus*, *Pentameris*, *Hypoxis*, *Limosella*, *Athrixia*, *Poa*, and *Trifolium*.

Mucina and Rutherford (2006) state that many of the genera of this belt show affinity with East African mountains (e.g. *Festuca*, *Koeleria*, *Merxmuellera* etc.). These areas consist of species-rich grasslands as well as short shrub-dominated vegetation with several

Fig. 3 Typical broad vegetation belts of the higher-lying mountains of southern Africa.

Fig. 4 Typical steep slopes, rolling plateaus and ravines of the Sub-Alpine vegetation belt of the Drakensberg region of southern Africa. Photo: LR Brown.

forb species. The grass *Merxmüllera disticha* and cushion plants, e.g. *Helichrysum sessilioides* and *H. praecurrens*, the latter forming low mats, are common in these areas. Other grasses that are prominent in this alpine belt include *Festuca caprina* and *Pentaschistis oreodoxa*. The “alpine everlasting” (*Helichrysum trilineatum*) as well as the dwarf shrub *Erica thodei* are common species that have adapted to surviving in this harsh environment.

Environmental and Ecological Drivers

Landscape and Climate

Mountains as prominent landscape features have a high habitat diversity characterized by high elevations, moderate to steep slopes and deep ravines, causing sharp climatic and ecological gradients. The peaks and slopes of mountains undergo a continuous process of erosion. On high elevation mountains, freeze-thaw events are the principal agents of rock weathering as well as soil heaving. Due to temperature fluctuations, rocks expand and contract, thereby causing small sections of rocks to be continually broken off. This is referred to as rock exfoliation (Van As et al., 2012). These series of changes, also referred to as periglacial processes, are normally slow and affect the soil structure that in turn affects the habitat of plant and animal species (Knight et al., 2018). Together with rock exfoliation, water erosion on the steep slopes causes the formation of gullies, ravines and valleys (Van As et al., 2012).

The different mountain ranges in southern Africa vary greatly in environmental conditions due to differences in longitude, topography, size, elevation, and aspect, as well as their distance from oceans. Mountain topography and aspect varies between areas, thereby creating micro-environments that may considerably differ from regional macroclimatic conditions. These micro-environments provide different habitats suitable for various plant and animal species. The sheltered environments normally have a higher rock cover, lower temperatures and lower evaporation rates. As a result, these protected areas normally have more nutritious soil, better moisture retention and a lush vegetation than unprotected areas (Van As et al., 2012). Due to habitat diversity, the vegetation of the Afromontane belt is structurally mixed and therefore not specific to any major physiognomic category (White, 1983).

Elevation has a significant effect on most climatic variables. Generally, an increase in elevation results in increased rainfall but decreases in temperature. Rainfall is regarded as a major driver of South African vegetation. Precipitation increases with elevation, which can be ascribed to the combination of rainfall and condensation from fog. In addition, the high mountain ranges also act as barriers that influence the flow of moist air-masses. Contributing to the variation in rainfall is the rain-shadow effect (Fig. 5). Most mountain ranges in southern Africa are situated along a north-south axis and intercept cool moist air drifting inland from the oceans. As a result, some slopes become wetter and others drier. This is referred to as the rain-shadow effect, and results in the vegetation on the drier slopes being dominated by dry woodland, savannah or karroid shrubland, whereas the wetter slopes are clothed in lowland forest (Van As et al., 2012). Although the average rainfall for these areas is approximately 1000 mm per annum, the wetter areas can receive as much as 1600 mm while the drier areas as low as 500 mm (Sene et al., 1998).

Fig. 5 Illustration of the rainshadow effect resulting in the southern mountain slopes being cooler and moister than the northern slopes.

Average temperature for these high lying areas (wet and dry) is 13°C and ranges between – 8 and 32°C. Throughout the year, cool daytime temperatures prevail. Frost and snow are common during winter with occurrence increasing with elevation (Mucina and Rutherford, 2006). Frost seldom penetrates more than 3–5 cm, resulting in only finer substrates being subjected to cryoturbation (Archibald, 1995). The many bare rock surfaces of these mountains contribute to pronounced daily temperature fluctuations with temperatures dropping below freezing at night and rising more than 15° during the day (Smith and Young, 1987). These temperature fluctuations, as well as temperature extremes, are responsible for the specific plant species composition. Only species that can adapt and survive these conditions are established here. Fog forms frequently throughout the year. In some areas the cold temperatures and snow negate the effects of high rainfall, resulting in drier environmental conditions than expected.

Wind

The frequency, magnitude and duration of the local wind regime at high elevations can influence plant growth and structure of vegetation (Gardiner et al., 2016). High wind speeds cool the leaf surfaces of plants, reducing the leaf- to- air vapor pressure deficit between the plant and the environment, which results in reduced transpiration and evaporation (Dixon and Grace, 1984). In some cases, the cool air can also lead to leaf mortality. Alpine plants are adapted to survive in these cold and windy conditions due to various morphological adaptations. According to Fitzgerald and Kirkpatrick (2017) graminoids, cushion plants and shrubs display a morphological response to wind by growing in the direction the most frequent damaging winds are blowing. Wind also plays an important role in seed dispersal of alpine plants. Tackenberg and Stöcklin (2009) found that alpine vegetation is dispersed over long distances due to the more intense vertical turbulence of alpine habitats.

Fire

Fire affects the general landscape of the ecosystem. According to O'Connor and Bredenkamp (1997) fire is vital in the maintenance of the structural and textural patterns of the vegetation. Fires are naturally caused by lightning strikes and, in rare instances, by rock falls (Van As et al., 2012). Sparks from hardened falling rocks (as a result of earth tremors, animal or human activity), causes veld fires when the dislodged rock strikes a spark on a boulder covered with highly flammable grass material (Edwards, 1984; Simons, 2017). Fire is a natural ecological factor in the grasslands and savannah of southern Africa. The Drakensberg region consists mostly of grasslands with the fynbos-alpine heath-like vegetation on mountain crests and plateaus. The vegetation composition and structure are maintained as a result of the climate and the role that fire plays in this high-elevation ecosystem. According to Granger (1976) and De Villiers and O'Connor (2010) the anthropogenic exclusion of fire from this ecosystem has resulted in a shift from grassland to thicket. Natural fires used to occur throughout the region, but with the development of high-elevation farming,

including the erecting of fences around farms and other properties, fires were kept out of these ecosystems. This resulted in changes in plant species composition and structure. Together with climate, fire is one of the most important ecological drivers responsible for maintaining the structure and composition of the vegetation on the high-lying mountains of southern Africa.

Animals

Generally, the mountain fauna is less distinctive than the vegetation, however, all of these species have adapted to these variable and harsh climatic conditions that persist in the area. One such species, the bearded vulture (*Gypaetus barbatus*) occurs in the high-elevation mountains of Drakensberg. This vulture is adapted to the cold conditions due to a downy insulating layer beneath its feathers. The strong winds prevailing at these high elevations allow them to effortlessly soar for most of the day in search of food (Van As et al., 2012).

Insects and other invertebrates are poikilotherms, meaning that their body temperatures are influenced and dependent on that of the surrounding environment (Clusella-Trullas et al., 2008). According to Chapman (2002) alpine insects are often dark since that allows them to absorb more solar radiation than light-colored ones. All the insect species of the alpine regions are also frost tolerant and can therefore endure the temperature extremes.

Likewise, poikilothermic reptiles, including lizards, are adapted to these cold conditions and make use of solar radiation to warm themselves in this cold climate.

The ice rat (*Otomys sloggetti*) is a natural mammalian inhabitant of high-elevation vegetation and is endemic to the southern African Alpine zone (Du Preez and Brown, 2011). Ice rats (Fig. 6) are diurnal, herbivorous, burrow-dwelling rodents that are adapted to these cold and wet conditions. During the day the rats forage and warm themselves on the rocks; during the night they move into their burrows where they huddle together for warmth and are thus protected against the cold night temperatures and strong winds.

Adaptations of Vegetation

The extreme environmental conditions present on mountains have a major impact upon organisms which live in these areas. The extremely low temperatures above and below ground, and long periods of low light intensity, have a major influence on plants and animals. Furthermore, strong, desiccating winds, snowstorms and permafrost conditions, where soils are permanently frozen except for the upper few centimeters, contribute to limit the survivors of these conditions to a well-adapted plants and animals. Due to these harsh environmental conditions the vegetation comprises low-growing, dwarfish plants.

The cold temperatures and shallow soil occurring in these areas are only suitable for smaller plants. Freeze-thaw cycles put further stress on plants. These plants contain cryoprotectants in their cellular cytoplasm to lower its freezing point. Cryoprotectants are solutes such as glycerol, glucose, fructose and other compounds that act as antifreeze to prevent the water in the cellular fluids forming ice crystals that may puncture cellular membranes (Daubenmire, 1974; Van As et al., 2012). Many plants living in these extreme environments do not shed their dead leaves. These marcescent leaves insulate the stem and branches, protecting them against the cold. Other plants such as *Helichrysum* spp. have a low, cushion-like growth form to survive the fierce cold winds on exposed habitats. The leaves of some rosette plants fold inwards at night, protecting the meristematic tissue and buds from

Fig. 6 The ice rat (*Otomys sloggetti*) basking in the sun on the Drakensberg. Photo: LR Brown.

extremely low temperatures and cold, desiccating winds (Daubenmire, 1974; Van As et al., 2012). The small or needle-like leaves of some plants not only protect them against cold temperatures, but also serve to reduce the amount of water lost to the environment via transpiration.

Although these mountain areas generally have high precipitation, the clear skies expose the vegetation to more direct sunlight than plants at lower elevations, resulting in a more rapid loss of water. Moss species in particular are well adapted to handle dry conditions. They do not have a proper cuticle and readily lose water from the cytoplasm and become desiccated as external ice is formed. Thus, they are poikilohydric, meaning that the intracellular water content drops as the water availability in the habitat drops. This mechanism prevents the formation of large ice crystals inside the cells (Daubenmire, 1974). Other water loss protection measures of plants include pubescent leaves. These densely packed trichomes help prevent moisture loss in dry climates and also isolate leaves from low air temperatures. Some plants have leathery or thick fleshy leaves with sunken stomata to protect them against excessive water loss.

The dominant grasses and dwarf shrubs are short in structure and generally well-adapted to survive in cold temperatures. These plants have thin leaves to protect them against cold temperatures and water loss and they grow quickly to produce seed during the short growing season. The location of their meristematic tissues close to the ground not only prevents damage of these tissues against grazing and fire, but more importantly against cold temperatures. Most of the grasses occurring at these high elevations and cold temperatures, are C3 plants. These plants are well-adapted to cold temperatures and they produce a higher percentage of crude proteins than C4 grasses, though their rate of translocation of the end-products is very low. Although it was previously believed that the lower CO₂ concentrations at high elevation are responsible for C3 photosynthesis, the latest research shows that these lower photosynthetic rates are due to cold temperatures (Wittmer et al., 2010).

The wetlands of these areas are also characterized by the presence of a variety of plant species. Typical wetland plants found at lower elevations cannot cope well with the cold conditions of high-elevation wetlands and are therefore absent from these peatlands.

Biodiversity and Conservation Importance

The natural environment of these high-elevation areas is very important from a biodiversity perspective. According to Mukwada et al. (2016) the mountain ecosystems in South Africa are biologically unique with a high biodiversity, species richness and ecosystem complexity. These areas act as important sites of plant refugia and as migration routes for various animal species (Brand et al., 2011).

Due to the high precipitation of these areas they are referred to as the water factories of South Africa. The presence of a large number of high-elevation wetlands not only purifies the water, but most importantly acts as water reservoirs that slowly release the water into river systems. The Maluti-Drakensberg region supplies water to the rivers (Orange River as well as the Vaal River catchment systems) of the lower-lying areas of South Africa and is regarded as the most important water catchment area for southern Africa, in particular Lesotho and South Africa.

High-elevation mountains are regarded as centers of evolution for flowering plants (Hörandl and Emadzade, 2011). Although species richness generally decreases with elevation the DAC is regarded as a plant diversity 'hotspot' with a diversity of plant species showing affinity to vegetation of the south-eastern Cape as well as that of mountains further north in Africa. Due to the harsh environmental conditions and large number of micro-habitats, these areas are normally high in endemic species (Nagy and Grabherr, 2009). There are approximately 2520 flowering plant species, of which 334 are endemic and 594 near-endemic to this area (Ezemvelo KwaZulu-Natal Wildlife, 2012). That means that nearly 37% of all plant species present are endemic/near-endemic (Fig. 7). The variety in landscape, ranging from steep slopes with shallow soil to protected ravines with deeper soil as well as the various plateau terraces, creates many micro-habitats that provide suitable conditions for a variety of plant species. The Drakensberg Mountains have only 20 vascular plant species in common with the high-elevation flora of east and northeast Africa. This can be ascribed to the unique ecological conditions of the Drakensberg region (Davis et al., 1994).

These areas are also characterized by the presence of a large number of peatlands. Peatlands are unique in terms of species composition and age, with the peat-forming process taking place over thousands of years (Du Preez and Brown, 2011). It is estimated that peat grows at an average of 1 mm per year. These peatlands provide habitat for a large number of plant and animal species some of them rare or endangered.

Approximately 250 different bird species have been identified within the Drakensberg Mountain area. One species (mountain pipit—*Anthus hoeschi*) is endemic while another six species are near-endemic to this ecoregion. Three globally-threatened bird species, namely the southern bald ibis (*Geronticus calvus*), Cape vulture (*Gyps coprotheres*) and the wintering lesser kestrel (*Falco naumanni*) also occur in this high-elevation region (Hilton-Taylor, 2000). Three endemic river frogs as well as three endemic lizards are found in this ecoregion. In terms of invertebrates, a recent study identified 61 different species, of which between 18% and 36% are endemic to the DAC (Amstrong and Brand, 2012).

The large number of endemic animal and plant species indicate this area to be of high conservation importance. The various animal species, especially the reptiles and invertebrates, are also strongly associated with the different plant communities of the area. According to Brand et al. (2011) these areas provide ecosystem services in acting as enormous carbon sinks and also play a role in climate amelioration.

Fig. 7 Endemic species of the Drakensberg region.

Threats to the Ecosystem

Due to the harsh climatic conditions that prevail, these areas are not highly productive. Furthermore, these ecosystems are not resilient and do not cope well with disturbances. People living in these areas utilize the vegetation mostly for the seasonal grazing of their livestock and in some cases the establishment of small agricultural fields. Areas that are heavily grazed cause degradation of the land that leads to the destruction of the native plants and animals of these areas. Many of these high-elevation ecosystems in South Africa are threatened by anthropogenic influences, of which overgrazing by domesticated animals forms the largest threat. In the country of Lesotho, the local people living in these high-elevation areas are dependent on these areas for their livelihood. Since this high-alpine vegetation comprises mostly sour grasses (meaning low productivity and palatability) the local herdsmen are highly dependent on the more palatable grasses occurring alongside and in the peatlands in summer (Du Preez and Brown, 2011). The livestock industry is a vital component of the economic and social structure of the people living in these areas. Unfortunately, many of the high-alpine grasslands and peatlands are overgrazed, due to mismanagement and incorrect grazing practices. This has caused large scale degradation of not only the grassland ecosystems, but also the peatlands in Lesotho (Du Preez and Brown, 2011). Large scale erosion has taken place in some areas, while species composition has been altered as a result of the overutilization (Fig. 8). It is therefore important that not only the needs of the people in the areas should be addressed, but most importantly that sustainable management plans are established and implemented to ensure the conservation of these sensitive ecosystems.

Towards the Future

Alpine plants are potentially susceptible to climate change in terms of species composition and structure. Unfortunately, there few detailed studies have been done on the sub-alpine belt vegetation of southern Africa, due to the difficulty in accessing these areas as well as difficulty in obtaining funding for such studies. Whereas various long-term resampling studies have been done on the European Alps that allow for some comparisons in species changes over time, very little information is available on the vegetation of these areas in southern Africa. It is, however, predicted that where these areas are currently dominated by C3 grasses, the number of species will decline and the extent of alpine areas will become smaller over time (Mucina and Rutherford, 2006). Other studies predict that there will be an elevational ascent of many grasses, forbs and low shrubs. It is expected that because of their low competitive ability, alpine species will decrease in number while species from the lower-lying areas, better adapted to warmer conditions, will increase in number. Rosbakh (2013) states that montane and subalpine species will decrease in number due to climate change. Knight et al. (2018) consider that rapid climate warming of these high-elevation mountains has already reduced the efficiency of periglacial processes, which in turn may result in a change in soil structure and micro-habitats, thereby affecting the vegetation composition and structure, as well as that of the associated animals. Various ecological, physical and anthropogenic processes influence the vegetation of these high-lying mountains in southern Africa (Fig. 9). As discussed previously, these different processes are all interlinked, thus a change in only one of these processes will result in a change of the ecosystem that will affect the plant and animal species present in these areas.

This alpine ecosystem in southern Africa is not currently under threat in terms of anthropogenic pressures, mainly due to large sections being conserved in the uKhahlamba Drakensberg Park and smaller conservation areas (Mucina and Rutherford, 2006).

Fig. 8 Large scale erosion of the high-elevation peatlands of the Drakensberg regions of Lesotho, due to incorrect grazing practices. Photo: LR Brown.

Although many areas are negatively affected by overgrazing, large sections are still natural. It is, however, important that these high ecosystem service areas are constantly monitored to detect any negative effects or signs of degradation. It is equally important that the local people depending on these areas for their livelihood are involved in any decision-making exercises to ensure sustainable utilization and conservation of these ecologically sensitive areas. By implementing long-term research and monitoring studies, more information on the vegetation and resilience of this ecosystem would become available. This could assist current and future generations to make scientifically defensible decisions on the management and conservation of these areas.

Fig. 9 Physical, anthropogenic and ecological processes that affect the plant species composition and structure of the southern African Sub-Alpine vegetation belt.

Abstract

The Alpine zone of the temperate mountains of Asia is found mostly in the Himalayas. In addition, some alpine areas occur in the Tibetan Plateau. These areas are located at the junction of two major biogeographic realms: the Indo-Malayan and the Palearctic. The period of plant growth is severely limited by low growing season temperatures and a very short frost-free period. The Alpine vegetation of the temperate mountains of Asia is characterized by dwarf shrubs growing close to the ground. Three main vegetation types are recognized in the Alpine Zone of the Himalayas: alpine grassland, *Juniperus* scrub community, and *Rhododendron* krummholz community.

Location, Distribution and Ecological Condition

The Alpine zone of the temperate mountains of Asia is found mostly in the Himalayas. In addition, some alpine areas occur in the Tibetan Plateau (Hong et al., 1999) as well as selected high mountain regions of the temperate region of Asia such as Mount Fuji in Japan (Nakamura and Krestov, 2007). The cold climate of the alpine zone in temperate mountains is caused by adiabatic air cooling, so that it resembles polar climate. However, few studies have been made on the alpine vegetation plant diversity in temperate mountains of Asia. Most studies on the diversity of Alpine plants in the temperate region of Asia come from the Himalayas. The Himalayan range dates back to ca. 40–45 million years, and includes the highest mountain of the world. This range separates the Tibetan Plateau from the Indian subcontinent. Moreover, these areas are located at the junction of two major biogeographic realms: the Indo-Malayan and the Palearctic. The region is characterized by mountains of simple slopes separated by deep river gorges and valleys. These mountain regions consist of a number of unique habitats, ranging from tropical jungles in the south to alpine zones in the north, due to the variation in topography and climate (Jamtsho and Sridith, 2015). The ecological condition of the Alpine zone of the temperate mountains of Asia similar to the alpine zones of other mountain ranges of the world, characterized by harsh climate with cold temperatures, high winds and abundant winter snow. The period of plant growth is severely limited by low growing season temperatures and a very short frost-free period (Pojar and Stewart, 1991).

Plant Diversity

Like the vegetation of other alpine regions of the world, the Alpine vegetation of the temperate mountains of Asia is characterized by dwarf shrubs growing close to the ground. Most of the alpine is treeless, but in the ecotone with the upper forest zone there are trees growing in krummholz form (Pojar and Stewart, 1991). According to a case study in the Eastern Bhutan Himalayas (Jamtsho and Sridith, 2015), three main vegetation types are recognized in the Alpine Zone of the Himalayas, as follows:

I. *Alpine grassland* (Fig. 1): This type of vegetation is rather common above the tree line up to the snow line (Tshuchida, 1991; Jamtsho and Sridith, 2015). It has a high diversity of herbaceous vascular plants including some selected grasses and sedges such as *Arundinella hookeri* Munro ex Keng, *Eragrostis nigra* Nees ex Steud. as well as *Juncus* spp. This fragile natural mountain meadow is mostly adorned by the luxurious growth of *Potentilla coriandrifolia* D. Don, *Bistorta* sp., *Cyananthus macrocalyx* subsp. *Spathulifolius* (Nannf.) K. K. Shrestha and shrubby *Rhododendron setosum* D. Don. The alpine soil is characteristically poor in nutrients and easily degraded by climate change, herbivore grazing, human activities, and rodents (Wen et al. 2010). The growth of herbaceous plants in the alpine community of the Himalaya is well supported because the steep slopes have curtailed most anthropogenic disturbances, such as animal husbandry Himalayan slopes are typically steep (angles over 45 degree) preventing easy access for grazing livestock. There are also no signs of environmental impacts by rodents. In the Bhutan Himalaya at Merak (Jamtsho and Sridith, 2015), it has been found that human intervention in the succession of natural alpine environment is comparatively low because of the lack of livestock grazing.

II. *Juniperus Scrub Community* (Fig. 2): This is a small community forming above treeline. It is mainly composed of dwarf *Juniperus recurva* Buch. -Ham. ex D. Don and *J. squamata* Buch. -Ham. ex D. Don. It forms rather scattered vegetation in the areas between the alpine grassland and the krummholz in the Himalayas. *Gentiana* spp. and dwarf *Rhododendron nivale* Hook. f. are some other common species found in this community (Jamtsho and Sridith, 2015).

III. *Rhododendron Krummholz Community* (Fig. 3): *Rhododendron* krummholz is another type of community forming above tree-line with a rich growth of bryophytes at the ground level. Krummholz is the dwarf, crooked and contorted trees that form small

Fig. 2 *Juniperus* Scrub community, Sakteng Wildlife Sanctuary, Trashigang district, Eastern Bhutan Himalayas. Photo: Karma Jamtsho.

clumps shaped by the wind. It is a mixed vegetation comprised of isolated patches of *Rhododendron* spp. Open grounds, gaps, and margins of such communities usually have a high diversity of herbaceous vascular plants, including *Potentilla saundersiana* var. *caespitosa* (Lehm.) Th. Wolf, various *Primula* spp., *Bergenia purpurascens* (Hook. f. & Thomson) Engl., *Oxygraphis endlicheri* (Walp.) Bennet & Sum. (Jamtsho and Sridith, 2015). The *Rhododendron* krummholz of the Alpine in the temperate zone of the Himalayas provides a microclimate that allows different plant species to co-exist. Therefore, this community also has rich diversity of herbaceous plants along with rigorous growth of *Rhododendron* spp. themselves. This community includes *Bistorta griffithii* (Hook.f.) Grierson (Polygonaceae), *Potentilla saundersiana* var. *caespitosa* (Lehm.) Th. Wolf (Rosaceae), *Bergenia purpurascens* (Hook.f. & Thomson) Engl.

Fig. 3 The *Rhododendron* Krummholz community, Sakteng Wildlife Sanctuary, Trashigang district, Eastern Bhutan Himalayas. Photo: Karma Jamtsho.

(Saxifragaceae), which generally flower in June. The same niche includes species of the same families that draw the same nutrients, including *Rheum acuminatum* Hook. f. & Thomson, *Potentilla fruticosa* var. *arbuscula* (D. Don) Maxim., and *Saxifraga hispidula* D. Don. These species flower in August approximately within the gap of 8 months. However, this plant community is damaged by animal grazing. Palatable plants are consumed, and unpalatable plants are trampled (Jamtsho and Sridith, 2015) (Table 1).

Abstract

Alpine soils, like alpine biota, have evolved under extremely cold climates. Snow cover has been a vital element of alpine ecology. The length and timing of the growing season are other essential aspects of the alpine. These climate-driven aspects of alpine environments are changing at a pace otherwise found only in the Arctic. Scientists can predict some of the likely effects of long-term warming on alpine soils and vegetation, but ecological relationships are often far more complex than we currently understand, especially in regions as remote and difficult to study as the tops of high mountains. What other unforeseen breakdowns in alpine ecological relationships will occur in the coming decades? We can only watch and wait to see what happens.

Introduction

Soils in the alpine regions of the world are generally thin, rocky, and frozen year-round. They are thin in part because they are young. Most alpine regions were covered by glacial ice during the last ice age, and today's soils have accumulated and developed only since that ice melted away. They are rocky because they lie in or near the paths of rock slides, rock fall areas adjacent to frost-shattered cliffs. The alpine landscape is also typically littered with rock debris left over from high-altitude glacial deposits. These rocks, ranging from pebbles to boulders, have become incorporated into postglacial alpine soils. However, the deposition of rocks is also an ongoing process in many alpine landscapes. The soils are frozen year-round because much of the alpine zone experiences a climate in which the average annual temperature is -2°C or colder. Anyone who has attempted to dig an alpine soil pit can testify that just a few cm below the surface is a rock-hard permafrost zone. One would think that alpine soils are too poor to support much vegetation, but this is far from the case. As [Körner \(2003\)](#) explains, alpine plants draw water and mineral resources from soils that are different in many ways from those at lower altitudes. There are a large variety of alpine soil types that change from one kind to another over very short distances. These soils range from alpine sand dunes to peat bogs, from shallow soils typical of steep alpine slopes to the much deeper soils of some alpine meadows. Alpine plant communities follow these below-ground patterns, so that soils and plant distributions are closely linked. This brief account of the nature of alpine soils aims to introduce their principal features and point toward threats to alpine soils from global warming.

Alpine Soil Characteristics

As mentioned above, alpine soils have unique characteristics. Many forces that shape alpine soils are associated with the cold climate regime of the high mountains. The climate data from Mount Evans, Colorado provides a typical example of North American alpine temperature regimes. Average winter high temperatures range from -11°C to -3°C between January and April. Average

winter low temperatures range from -22°C to -16°C , and never get above freezing, even in the summer. The climate data from the Matterhorn provides a typical example of high elevation temperature regimes in the Swiss Alps. Average winter high temperatures range from -11°C to -7°C between January and April. Average winter low temperatures range from -16°C to -8°C , and remain below freezing throughout the year.

Large Scale Processes and Landforms

Butler et al. (2009) described geomorphic patterns and processes that shape alpine landforms and soils, using research from Glacier National Park, Montana as the basis for their observations. At large scales (e.g., across valleys), the alpine landscape is shaped by avalanches, debris flows, landslides, and rock fall. Talus deposits that accumulate beneath rock falls may descend well below treeline (Fig. 1).

Medium Scale Processes and Landforms

At a medium scale, some alpine surfaces do not support vegetation except mosses and lichens. Examples of these inhospitable areas include talus deposits, avalanche boulder tongues, and solifluction lobes. These lobes (Fig. 2) are composed of alternating “treads” and “risers,” as are found on stairs. Turf-banked terrace risers are difficult sites for seedling penetration because of the dense covering of alpine vegetation, such as *Dryas octopetala*. Solifluction treads are equally difficult sites for seedling establishment because of their exposure to wind and drying, which makes the soil impenetrable to seeds.

Fine Scale Processes and Landforms

Fine-scale processes such as frost heaving and churning are inimical to the survival of most alpine plants, whereas other processes such as turf exfoliation may facilitate seedling establishment by creating microsites that are less compacted, more penetrable by seeds, and are sources of moisture retention. Turf exfoliation is process active in periglacial areas in which frost heaving destroys continuous ground vegetation cover by removing the soil exposed along small terrace fronts. On their leeward side, boulders resting on an alpine surface offer shelter to young plants where the microclimate might otherwise be too harsh for their survival. Needle-ice pans are ovoid to circular depressions 1–6 m in diameter with a steep scarp 20–40 cm high, affected by exfoliation. The pans may originate from animal trampling and hoof disruption of the turf surface. The surface of pans frequently show well-developed frost sorting and fine-scale patterned ground.

Fig. 1 Talus slope, Cascade Mountains, Washington State, by Laurel Fan (deceased, 2016).

Fig. 2 Solifluction lobes on mountain slope near Nome, Alaska. Photo courtesy of Oak Ridge National Laboratories.

Soil Formation

Alpine soils have been described by Schmid et al. (2019). Alpine soils near treeline in Glacier National Park (GNP), Montana, have traditionally been considered to be shallow, Lithic Cryochrepts with minimal horizon development. Cryochrepts are cold-climate soils lacking in development at both the surface and sub-surface levels (Fig. 3). These soils are thin but with well-developed O2 horizons and stony to very stony sandy loam to sand A, B, and C horizons.

Schmid et al. (2019) described the typical soils characterizing seven types of alpine microenvironments. These environments range from dry windblown sites to wet meadows and semi-permanent snow pack localities. Thus, topographic site conditions are the most important factor in alpine soil development because they control both snow cover and loess distribution, which in turn influence the rate of soil development.

Sources of Soil Materials

Soil development in more temperate climates involves considerable chemical weathering. But in high-mountain soils, the chemical reactions associated with chemical weathering have been considered by soil scientists to be inhibited by very cold temperatures, often to the point of non-occurrence. The general perception of weathering in alpine soils has been that mechanical processes predominate, with “freeze-thaw” weathering as the primary agent. However, contrary to this temperature-inhibited model, several recent studies have shown that chemical weathering does occur in cold alpine regions, and that the process is mainly controlled by moisture availability. Furthermore, since weathering rates decrease over time, the availability of fresh mineral surfaces derived from physical erosion influences or determines chemical weathering rates (Egli et al., 2014).

Alpine soil formation rates have been estimated at about 320–450 tons per km² per year. Using a method called the known surface age and soil thickness approach, Egli et al. (2014) used age constraints based on dated surfaces (e.g. moraines) to estimate soil formation rates by relating soil profile thickness to surface age. Their results show alpine soil formation easily reaches rates of up to 800–2000 tons per km² per year. Previous alpine soil studies have shown that particularly young soils intensively weather, even under continuous seasonal snowpack. These findings cast doubt on the concept of ‘temperature-controlled’ soil development in alpine regions.

As discussed by Körner (2003), there are four principal sources of accumulation of fine mineral substrates in alpine terrain: (1) local erosion of parent rock, (2) movements of sediments by gravity (on and below slopes), (3) sedimentation by water or snow (avalanches etc.), and (4) sedimentation by wind. Because of the presence of permafrost in alpine soils, cryogenic processes play a role in deposition from all four sources. The coarse matrix into which finer sediments fill is created by landslides, glacial deposits, scree accumulation or solid rock weathering. In this coarse matrix, fine sediments accumulate from the bottom up, only slowly reaching the soil surface.

The accumulation of fine particles by eolian deposition is a particularly important component of alpine soil formation. Dust deposition is enhanced in the alpine zone, especially in younger mountain ranges, which include nearly all the large mountain ranges of the world. As discussed above, physical weathering of rocks in the alpine provides a steady source of newly eroded sediments. The erosion of surfaces by alpine glaciers generates large quantities of silt. Thus, in glaciated mountains, this silt is a particularly significant dust source. Mountain winds stir this dust up and redeposit it over alpine landscapes. It accumulates in

topographic depressions and on vegetation. A steady supply of loess (wind-blown silt) causes alpine soil profiles to contain large fractions of very fine grain sizes.

Permafrost and Periglacial Features

Most alpine soils are in permafrost. In summer, a relatively shallow active layer thaws, providing a suitable substrate for alpine vegetation. However, the roots of alpine plants are shallow, because they cannot penetrate the permanently frozen ground beneath the active layer. Alpine permafrost may consist of solid rock with ice-filled joints, fine grained soils containing segregation ice, ice-supersaturated gravels, where not all particles are in contact, or dirty ice with some dispersed solid particles distributed within the ice (Harris et al., 2009). Segregation ice forms as discrete layers or lenses of ice develop in freezing mineral or organic soils, as a result of the migration and subsequent freezing of pore water.

Cryoturbation

As discussed by Pollard (2018), cryoturbation, or frost heaving, involves soil movements due to frost action. Frost heave is the upward movement of soil and rock due to frost action (Fig. 4). It occurs where climates are so cold that freezing temperatures propagate below the ground surface. If there is enough soil water and the soils are frost-susceptible, the cold soils cause ice lens formation. Water migrates from nearby unfrozen soils toward the ice lens by capillary action. This type of enhanced ice formation is called ice segregation.

Cryoturbation causes the mixing of materials from various soils horizons down to bedrock due to freezing and thawing. The extent of cryoturbation in alpine soils varies considerably. It is much more common on exposed sites than in sheltered sites such as alpine valleys (Fig. 5). In the autumn, cold nights cause alpine soils to freeze, and relatively warm days melt the frozen soils. These freeze/thaw cycles generate lenses of ice that form when meltwater penetrates down in the soil. As this freeze/thaw process continues, the soil in the active layer gradually loses moisture. This water percolates down to the permafrost boundary. The dried,

frost-heaved soil at the surface forms granular structures. Separation of coarse from fine soil materials produces distinctive patterned ground in various alpine soils.

Frost boils are one expression of alpine cryoturbation. These are small circular mounds of fresh soil material formed by soil upheaval and needle ice formation (Fig. 6) in frost-disturbed ground.

One might think that such highly disturbed substrates would be unsuitable for plant seedling establishment, but this turns out not to be the case. Frost boils have been found to provide “safe sites” for recruitment because these bare patches have reduced competition from other plants for space, light, and nutrients, and so they take advantage of the gap in the vegetation cover. In a study of alpine seedling establishment in and around frost boils, Sutton et al. (2006) found that the optimal location for seedling establishment is at the frost boil’s edge, and seedlings decreased near the center where the level of disturbance is at a maximum.

Because of the highly variable topography and parent material of alpine soils, there are a variety of different soil textures and soil water is unevenly distributed. These variable features, plus the movement of soil water as soils freeze, create differential frost heaving and the preferential heaving of objects buried in the soil. Fine-grained soils may move by frost action during the thawing phase. This combined with the frost heaving during freezing produces a convection-like system that contributes to the formation of various forms of patterned ground (Fig. 7), as well as the downslope creep of sediments on slopes.

Patterned Ground

Patterned ground may be seen where there is a ground surface showing an ordered, more-or-less symmetrical, morphological pattern of ground. Patterned ground associated with cryoturbation is common in alpine regions where there is intensive frost action. In permafrost regions it is limited to the active layer. The patterns include sorted and non-sorted circles, polygons, nets, stripes, and steps.

Solifluction

Frost action on slopes also results in the development of large lobes that slowly migrate downslope, a process called solifluction. In permafrost regions, this process is differentiated by the attribution of the name “gelifluction.” Gelifluction is prominent in alpine regions where snow falls during 6–8 months of the year. Solifluction is a form of slow, creep-based mass movement of waterlogged soils that reflects the combined effect of gravity and freeze/thaw activity on gentle to moderate slopes in periglacial environments. Repeated freeze/thaw of slope sediments results in the incremental downslope displacement of materials by a process called frost creep. Surface displacement rates in gelifluction range from several millimeters to several tens of millimeters per year. In a study of gelifluction in the Tianshan Mountains of China, [Gengnian et al. \(1995\)](#) found the mean surface rate of movement to be 11.14 cm per year, but that not all parts of the lobes move at the same speed. The leading edge of the Tianshan gelifluction lobes moved at a rate of 1.86 cm per year. The rate of movement at the center of the lobes (3.1 cm per year) was greater than at the sides (0.86 cm per year).

Nivation

Nivation is the erosion of the ground beneath and at the sides of a snow bank, mainly as a result of alternate freezing and thawing. Since snow banks tend to form in the same alpine localities year after year (the leeward side of boulders, topographic depressions), the repeated erosion eventually creates a nivation hollow ([Fig. 8](#)). This is a self-perpetuating process, as seasonal or perennial snow cover causes erosion that deepens existing hollows, in which more snow is likely to accumulate in the future.

Impacts of Climate Change

Global change is already bringing higher temperatures to alpine regions around the world. Mountain temperatures are increasing far more quickly than the global average, at a rate closer to that of the Arctic ([MRI EDW Working Group, 2015](#)). Accelerated mountain warming may be due to loss of albedo. Mountain peaks are losing their highly reflective blankets of snow and ice that return much of the sun’s radiation back to space. Instead, darker-colored ground absorbs heat, amplifying the heat-trapping effect of greenhouse gas pollution.

Fig. 8 Nivation hollow in the Cairngorm Mountains, Scotland. Photo by Ash Green, used with permission.

Snow Cover

As discussed by [Edwards et al. \(2007\)](#), one of the vulnerabilities of alpine ecosystems is their reliance on snow cover for much of the year. Various aspects of the relationships between alpine soils and plants that experience seasonal snow cover are susceptible to major perturbations if the snow cover duration and thickness decline because of climatic warming. In particular, the number, frequency and duration of freeze/thaw events influence the nature of nutrient and carbon cycling. Freeze/thaw events disrupt soil structure and act as a selective anti-microbial agent. Soil microclimate is particularly important in alpine ecosystems, responding to changes in water movement and nutrient cycling that are affected by larger scale increases in temperature and changes in precipitation ([Winkler et al., 2019](#)). With declines in snowpack brought on by climate change, alterations are expected in soil N availability, soil organic matter and water holding capacity, soil pH, and even soil texture, all of which may lead to both direct and indirect effects on alpine flora.

Winter temperatures beneath alpine snowpack are substantially warmer than the adjacent air temperatures. A study of temperatures beneath snowbanks in Svalbard showed that temperatures beneath 30 cm of snow remained extremely stable and did not fall below -2°C , even though air temperatures above the snow dropped as low as -24°C ([Convey et al., 2015](#)). This subnivean habitat is vitally important to a host of organisms. Subnivean temperatures influence the kinetics of microbially mediated metabolic and transformation processes. Edwards et al. identified three key snowpack periods based on the length and general significance of contrasting physical conditions. These included a pre- and post-snowpack period likely to experience freeze/thaw conditions with a relatively stable middle period of continuous snow cover. As discussed by [Winkler et al. \(2019\)](#), changes in the timing of snowmelt will dictate changes in growing season length and seasonal soil dry-down rates. They will also create differences in soil nutrients including nitrogen and phosphorous as well as soil pH levels.

Permafrost Degradation

Experimental warming-induced degradation of permafrost in an alpine meadow on the Tibetan Plateau caused an exponential decrease in soil organic matter, which made the soil more gravelly and coarse ([Winkler et al., 2019](#)). Furthermore, soils at colder, high-elevation sites shifted further toward coarser soil textures than warmer, low-elevation alpine sites. Declines in organic matter and coarser soil texture reduce water-holding capacity, which is expected to have consequences for alpine plant communities. These studies also showed that warming increased soil respiration rates only when adequate soil moisture was available.

Alpine Soil Changes

As we have seen, the warming of alpine soils is predicted to bring increased nitrogen availability through greater efficiency of soil microbe decomposers. The increased availability of nitrogen will likely enhance plant growth and reproduction. However, this may be offset by decreased available moisture where summer rainfall is insufficient to maintain soil moisture through a longer, warmer growing season.

Alpine soils can contain more labile soil organic matter than soils from lower elevations because of the slower decomposition and biochemical transformation at colder temperatures.

As discussed by [Pellissier and Rasmann \(2018\)](#), in cold alpine regions, rates of organic matter decomposition from soil organisms decrease with elevation, while organic matter and carbon storage increases. These features of alpine soils will necessarily change under a warmer climatic regime. In future, rates of organic matter decomposition will increase, while organic matter and carbon storage decrease. Soil carbon stocks will decline because warmer soils increase soil respiration.

The loss of soil organic matter will likely bring about a coarsening of alpine soils, as shown in the study of warmed soils on the Tibetan Plateau ([Winkler et al., 2019](#)). They also observed that soils at colder, high-elevation sites on the plateau shifted further toward coarser soil textures than warmer soils in low-elevation alpine sites. Finally, coarse-grained soils retain less water than soils with strong fine-grained components. This decreased ability to hold water will compound the problem discussed above, wherein longer summers and declining snowpack will tend to dry alpine soils, regardless of the predicted decline in soil water retention capability.

Conclusions

Alpine soils, like alpine biota, have evolved under extremely cold climates. Snow cover has been a vital element of alpine ecology. The length and timing of the growing season are other essential aspects of the alpine. Mathematical modeling and limited field observations combine to predict some of the likely effects of long-term warming on alpine soils and vegetation, as discussed here. But ecological relationships are often far more complex than we currently understand, especially in regions as remote and difficult to study as the tops of high mountains. What other unforeseen breakdowns in alpine ecological relationships will occur in the coming decades? We can only watch and wait to see what happens. But just as the alpine flora and fauna cannot migrate to colder environments because they already live on the tops of mountains, so also alpine soils will have no colder place to develop in the face of climatic warming. In other words, the whole alpine ecosystem is endangered by global change, from the bottom up.

Abstract

This article deals with insect adaptations for life in the alpine zone, primarily in the middle and high latitudes. Their behavioral adaptations are mainly focused on seeking shelter from winter air temperatures. Their physical adaptations include small body size and dark-colored exoskeleton. Most alpine insects are flightless. Their physiological adaptations include freeze resistance, freeze tolerance, and cryoprotective dehydration. Their enzymes are geared to work at low temperatures. Because alpine vegetation is often sparse and grows slowly, plant-feeding species represent a very small proportion of the insect fauna. Many alpine insects are predators or scavengers that rely on arthropods from lower elevations for their food. These insects and spiders are blown up onto the alpine landscape by upslope winds. The life history adaptations of alpine insects include multi-year life spans, especially of larvae and adults, as well as adaptations in their phenology: the timing of periodic events in their life cycle.

Introduction

Insects, like other invertebrate animals, cannot regulate their own body temperatures except by behavioral means such as basking in the sun or burrowing in the soil. In regions such as the tropics, where temperatures are generally both warm and stable throughout the year, this aspect of insect physiology puts little or no environmental stress on insects. However, seasonality and cold temperatures increase in the higher latitudes and at high elevations, and winter air temperatures become lethal to insects in the alpine regions. This article deals primarily with insect adaptations for life in the rarified air of those mountaintops.

Insects have many ways of dealing with cold climates. Surprisingly, the one adaptation that is utilized by very few alpine insects is migration to lower elevations during winter. Nearly all alpine insects and other invertebrates remain there throughout the year. Their behavioral adaptations are mainly focused on seeking shelter from winter air temperatures. Their physical adaptations include small body size and dark-colored exoskeleton. Their physiological adaptations include freeze resistance, freeze tolerance, and cryoprotective dehydration. Their life history adaptations include multi-year life spans, especially of larvae and adults, as well as adaptations in their phenology: the timing of periodic events in their life cycle. Each of these topics are discussed in some detail, below, after a brief discourse on the natural history of alpine insects.

Alpine Insect Life

There are important differences between Arctic insects and those living at high altitude, because the environmental characteristics of these regions are quite different, in spite of their similarities of cold temperature regime (Mani, 1968). Atmospheric pressure decreases with altitude. In the alpine zone above treeline, atmospheric pressure is only 40–60% of that at sea level. Low atmospheric pressure has a wide range of effects on alpine environments. The thin air is highly transparent to incoming solar radiation (insolation). However, the air holds less heat than the denser air closer to sea level, so the alpine climate is cold. The thin air also holds less moisture, making alpine air quite dry. The lack of moisture also reduces the greenhouse effect, which leads to large differences between daytime and night time temperatures. The cold air temperatures cause most of the alpine precipitation to fall as snow. The thin air also does a poor job of screening out ultraviolet radiation, so UV levels are high in the alpine. The aridity of the air leads to greater rates of moisture evaporation from exposed surfaces. This causes rapid desiccation of soft-bodied invertebrates. The

Fig. 1 The ecological importance of cold climate for alpine insects. After Mani, M.S. (1968). Ecology and biogeography of high altitude insects. The Hague: Dr. W. Junk Publishers.

high levels of insolation also cause rapid heating of insect bodies in the summer. Mani (1968) argues that the cold temperatures of the alpine regions are crucial to the survival of high altitude insects, as the cold air keeps insects from overheating in the intense sunshine. It also tends to counteract the aridity of the region and it slows the rate of moisture evaporation from exposed surfaces.

The ecological importance of cold climate is summarized in Fig. 1. Cold temperatures drive both behavioral responses and physical adaptations in alpine insects. The alpine regions are generally inhospitable to insects and other invertebrates. The winters are very long and incredibly cold, with potentially lethal air temperatures persisting for several months of the year. Summers are short, and the length of the growing season decreases with elevation. The growing season in high elevations above treeline average 50–60 days. The highest peaks have only sparse, intermittent plant cover. Thus, the diversity of plant feeding insects is low here.

Because of the thin air, summer daytime temperatures in the alpine vary greatly, depending on location. As shown in Fig. 2, the temperature on a rock surface exposed to the sun may be 30 °C, while the temperature in the shade may be –5 °C. At the same time, the temperature in a pocket of air just beneath a stone is considerably buffered (7 °C) (Mani, 1968). In order to maintain a more-or-less stable internal temperature, alpine insects must continually select suitable microhabitats.

Alpine Insect Life Cycles

Danks (2006) discussed the ability of cold-adapted insects to accelerate the development of their life stages in regions with short growing seasons, such as the alpine. Faster development is assisted by more rapid metabolism (at a given temperature), by reducing the amount of heat required for development, by low threshold temperatures for development, by adaptations of structure or color to assist heat gains, and in several other ways. The average temperature threshold for development in insects is about 10 or 11 °C. Some species from cold habitats such as the alpine have much lower developmental thresholds. For example, winter crane flies of the genus *Trichocera* develop at temperatures as low as –1.5 °C and cold stream stoneflies develop in water that is only 1 to 2 °C. Many alpine species are active at temperatures below freezing.

In winter, almost all alpine insects enter an essentially inactive state called diapause. This is a form of developmental arrest in insects that allows them to survive frigid winter conditions. Some cold-adapted insect species are capable of entering diapause several times. This adaptation facilitates their survival for several years in cold regions where this may be required for the completion of development.

A few groups of plant-feeding insects thrive in alpine environments, including leafhoppers, and grasshoppers. High-altitude grasshoppers rely on an extended life span to overcome the rigors of the climate. Most low altitude grasshoppers overwinter in the egg stage. These eggs hatch in spring, then rapidly proceed through the immature stages (nymphs) and become adults within a few weeks. But the maturation process requires warmth, and that is in short supply in the alpine. Lower elevation hoppers become

Fig. 2 Differences in temperature in alpine microclimates. The shady side of a rock may be 25 °C colder than the side exposed to the sun. The temperature in an air pocket beneath the rock is buffered.

adults in as little as 30 days, but this process can take almost twice as long at high elevations. High altitude grasshoppers often overwinter as nymphs. This strategy gives them an early start on the maturation process when warm weather arrives in the alpine. Some alpine species stretch their life cycles into more than 1 year, passing the first winter in the egg stage and a second winter as a nymph. Adults also occasionally survive the winter. Late developing species commonly survive until the first severe frost while adults of early developing species may die in mid-summer.

Aquatic alpine insects have a number of adaptations to cope with cold climate and short growing season, as discussed by [Danks \(2007\)](#). These include the use of widely available foods, increased food range, prolonged development (including development lasting more than 1 year per generation), programmed life cycles with diapause and other responses to environmental cues, often enforcing a strict univoltine life cycle and staggered development. Univoltine insects are those that lay just one batch of eggs per year. The response of alpine aquatic insects to the onset of winter conditions may be met by diapause as well as by movement to terrestrial habitats, to less severe aquatic habitats, or to different parts of the same habitat, and by construction of shelters.

Alpine streams are characterized by high solar radiation, year-round low air and water temperatures, scarce vegetation, and a short snow-free season. Many alpine streams drain glaciers at the tops of their catchments. [Schütz and Füreder \(2018\)](#) examined the growth and development of alpine midges (family Chironomidae) in a highly glaciated headwater stream in the Austrian Alps. Water temperature at the site closest to the glacier ranged from 1.1 °C in mid-August to 0.3 °C in early October. Only a few highly adapted midge larvae (genus *Diamesa*) live in these extreme conditions. The study showed that larval size and volume increases in close proximity to the glacier. These are the coldest stream waters of the alpine zone, but they contain higher levels of benthic organic matter toward the glacier. Because these midge larvae are some of the most cold-adapted in the world, they can take advantage of the increased food availability in highly glaciated alpine headwaters. The harsh conditions in these environments (low temperatures, high turbidity and flow dynamics) apparently exclude most midge taxa, but favor these highly adapted species, when their essential needs (food quality and quantity) are guaranteed.

Melanism and Reduced Body Size

Most alpine insects are darker in color and smaller in size than species that live at lower elevations. In species that have ranges that span many life zones, there are often population differences, with alpine specimens being the darkest in coloration and smallest in size. Melanism is an adaptive response that makes the most of limited solar warming in cold regions. Absorption of solar energy by the exoskeleton warms the insect's internal organs, facilitating activity at lower temperatures. As shown in [Fig. 3](#), there are various factors that stimulate the development of dark pigments on insect exoskeletons. Among these are the high levels of ultraviolet radiation and solar radiation of high elevations. High levels of pigmentation protect insects from UV damage to internal tissues. Darker bodies absorb more heat from the insolation, a critical aspect for high-altitude insects living in perpetually cold conditions. However, dark surfaces not only absorb solar energy more effectively, they also lose energy more readily. Alpine insects must try to gain more heat during the day than they lose at night, as their bodies emit infrared radiation back into the atmosphere.

Fig. 3 Above: environmental factors that stimulate melanism in alpine insects; below: benefits of melanism to alpine insects. Concepts from Mani (1968).

A notable example of increased melanism with elevation can be seen in specimens of the butterfly *Parnassius clodius*. This species ranges widely throughout western North America. High elevation populations, found in alpine meadows, have broad dark bands on both the forewings and hindwings, as well as large red spots on the hind wings (Fig. 4A). Its lower elevation populations, found in montane meadows, have a white ground color on the wings, rather narrow dark bands on the forewings, and small red spots on the hind wings (Fig. 4B).

Orthoptera, the insect group that encompasses grasshoppers and bush crickets, includes a particularly large number of species that are color polymorphic with a marked green-brown polymorphism being particularly widespread. It has repeatedly been reported that orthopterans raised under cool conditions are darker than those raised under warm conditions. Valverde and Schielzeth (2015) tested for the effects of background color and ambient temperature on the occurrence of color morph switches (green to brown or brown to green) and developmental darkening in the alpine dwelling club-legged grasshopper *Gomphocerus sibiricus*. Their results indicate that melanin, a multipurpose pigment responsible for dark coloration, seems to be strategically allocated according to environmental conditions. Unlike other grasshoppers, the species is apparently unable to switch color morphs (green/brown) during development. Thus it appears that this darker form is determined genetically, or very early in development.

Most alpine insects have smaller bodies than low elevation species, as discussed by Mani (1968). He noted that species of the ground beetle genus *Bembidion* that live from 2500 to 3000 m elevation range in size from 8 to 13 mm in length. Species that live from 3000 to 4000 m in the Himalayas are 5–8 mm long, while species that live above 5000 m range from 2 to 4 mm in length. As discussed below, the vast majority of alpine beetles are flightless. The reduction in size, or total absence of wings, is associated with smaller body size in beetles at all elevations. The cold climate and lengthy period of diapause of alpine insects slows down the process of insect metamorphosis, limiting the time for growth and development of the various life stages to a few short weeks

Fig. 4 Differing levels of melanism expressed in different populations of the butterfly *Parnassius clodius*. (A) Note the broad dark bands on both the forewings and hindwings, as well as large red spots on the hind wings of a specimen from an alpine population; (B) note the poorly developed dark bands and small spots on the hind wings of a specimen from a low elevation population. Photos by Jeff Pippen, used by permission.

of summer. This limitation is also thought to put selective pressure favoring reduced body size of alpine insects. Small body size also allows alpine insects to shelter in nooks and crannies where the microclimate is most suitable.

Many alpine insects are clothed in scales, bristles, and hairs (setae) that provide some measure of insulation from cold air by trapping small pockets of air around their bodies. This is especially important for insects that spend time on snowfields, where chilling would otherwise be fatal. Some of these insects also have a waxy coating on their bodies that helps prevent desiccation.

Brachyptery

Brachypterous insects have very reduced wings, so that they are unable to fly. This is a common feature of some alpine insect groups. Apterous insects have no wings, so are likewise flightless. [Darlington \(1943\)](#) noted early on that alpine beetles (especially the family Carabidae, or ground beetles) are mostly flightless. There are several reasons why brachyptery is an advantage to alpine insects. First, the alpine regions are the windiest regions of the world, often experiencing hurricane-force winds. In such conditions, wings are a handicap, not an advantage. Alpine insects live on patches of treeless mountaintops, surrounded by montane forests. From an ecological perspective, the alpine regions are considered habitat ‘islands,’ surrounded by a ‘sea’ of lower-elevation forests, where alpine insects do not belong. The flightless habit of alpine insects, such as beetles, keeps them from being blown off the mountain tops, down to lower elevations. This is not the case for some important alpine insect groups, such as butterflies and moths (Lepidoptera) and flies (Diptera), but even these flying insects tend to stay very close to the ground in the alpine. [Table 1](#) shows the percentage composition of apterous and flightless species in some important alpine insect orders and families in the northwest Himalayan region. [Hiramatsu and Usio \(2018\)](#) studied the species composition of ground beetles in a mountain wildlife reserve in Japan. They identified 23 taxa living in the subalpine and alpine zones of Mount Hakusan. Of these, 12 were apterous, and 7 were brachypterous. Further downslope, the ground beetle fauna of a nearby grassland contained about 75% macropterous (fully-winged) species ([Fig. 5](#)).

Table 1 Percentage composition of apterous and flightless species in some important alpine insect orders and families in the northwest Himalaya.

Order or family	Percentage of apterous species	Percentage of flightless species
Orthoptera (grasshoppers, katydids, crickets)	70	25
Dermaptera (earwigs, pincer bugs)	100	0

Behavioral Adaptations

Temperature thresholds for development and activity are commonly very low in alpine species. Relatively low summer temperatures are offset by development at low temperatures, by selection of warm habitats and microhabitats, and in adults by thermoregulation and modified mating activity. As mentioned above, those alpine insects that do fly generally fly very close to the ground, where heat reflected from the soil creates a warm microhabitat. Resting adult insects often select particularly warm sites, such as locations with dark surfaces, as well as inside the heads of flowers that have a parabolic shape to trap solar energy. Basking in the sunshine is an important behavior for flying insects, as they need to warm their flight muscles before they can fly.

Aquatic insects in alpine ponds and streams have some interesting behavioral adaptations to bitterly cold winter temperatures (Fig. 6) as discussed by Danks (2007). A few species move during winter to resist anoxia beneath ice. High stream flow rates and ice scour take place in spring. These environmental threats may be withstood or avoided by wintering in less severe habitats, penetrating the substrates of streams and ponds, or by delaying activity until after peak flow. However, the growing season is so short in the alpine that many species become active as early as possible in the spring. This trait is enhanced in some pond habitats by choosing overwintering sites that warm up first in spring.

As discussed above, larvae of the midge genus *Diamesa* are adapted to live in the coldest of alpine streams where the spring/summer melt brings dangerously high water volumes and scouring ice. As discussed by Danks (2007), most other midge and other aquatic larvae develop lower in the channel during winter and so avoid the disturbances of summer. Alpine streams fed by melting snowbanks and rainfall are warmer and much less turbid than those fed by glaciers, with peak flows in spring. The diversity of aquatic insect species increases with distance downstream from mountain tops. Streams that are fed at least partially by groundwater tend to have more constant temperature and flow, and chemical characteristics that depend on the water sources. Alpine streams that serve as lake outlets provide yet another set of habitats. Different habitats within streams differ in hydrology, especially the major spring peak from melting ice and snow, but they also differ in warming and cooling rates as well as heat accumulation. In alpine aquatic habitats, key climatic elements influencing the insect fauna arise from seasonality and variability. Food supply is also important.

In most aquatic alpine habitats options for heat gain by immature stages are limited, and therefore site selection plays a key role in ponds. In cold regions, mosquito larvae tend to aggregate in the warmest places in the pools where they develop, preferring sunny to shaded locations and even adjusting their depth to select places closer to the preferred temperature. Chosen sunny sites can be as much as 6 °C or 7 °C warmer at the same time of day than other parts of the same pond that are cooled by permafrost and lack insolation. Many species from cool streams are cold stenotherms that are active at low temperatures. Eggs of stoneflies (Plecoptera) are cold adapted, and many larval stoneflies develop at very low temperatures. Some larval mayflies (Ephemeroptera) and caddisflies (Trichoptera) are active at temperatures below 0.5 °C. Many rapidly developing species are small, a trait that reduces requirements of heat as well as food.

Crowding—the massing together of large numbers of insects—is a well-known behavior of insects on mountain tops (Mani, 1968). The frequency and intensity of crowding increases with elevation in high mountain regions. This makes sense ecologically, because the number of suitable insect habitats likewise decreases with elevation. So high alpine insects are found crowded together in the few microhabitats where they can survive the environmental extremes of high mountains. It is interesting to note that many

Fig. 6 Flow chart illustrating alpine aquatic insect adaptations.

different species of arthropods, often from quite different taxonomic groups, are found crowded together in isolated pockets of alpine landscapes. The author has often seen several different predatory ground beetles, rove beetles and spiders, sheltering under the same stone in alpine meadows in the Colorado Rockies. This overcrowding into numerous isolated groups slows growth rates, limits body size, structure and color (favoring melanism) (Mani, 1968).

Dietary Adaptations

The short growing season and cold climate lead to a paucity of food resources in the high alpine. For aquatic insects, all of the normal food sources insects tend to be reduced. First, terrestrial vegetation surrounding aquatic habitats is less rich and diverse in the alpine, limiting allochthonous (from outside sources) inputs of litter (Danks, 2007). In particular, trees are absent in the alpine zone, reducing the autumn pulse of deciduous leaves that characterize temperate habitats. Decaying leaves in streams supply the coarse particulate organic matter on which many stream insects depend. Second, other organisms that serve as food for predatory insects are reduced these in cold, unproductive habitats. Third, cold conditions slow the growth of periphyton in streams, thereby limiting autochthonous (indigenous) food. Periphyton consists of the freshwater organisms attached to or clinging to plants and other objects projecting above the bottom sediments, including algae and cyanobacteria. Plankton growth in many lakes is likewise inhibited by low temperatures and low nutrient levels.

Alpine vegetation cover is sparse in many places. It grows slowly and never more than a few cm above the ground. Food for phytophagous insects is thus in relatively short supply. Because of this, the normal trophic system, or ecological pyramid, is turned upside down. In other ecosystems, the phytophagous species are most diverse and abundant while predatory species are relatively few and rare on the landscape. In the alpine, plant-feeding species represent a very small proportion of insect species. Mani (1968) reported that only 3% of insect species in the high alpine regions of the northwest Himalaya are phytophagous. The rest either feed on various kinds of organic debris, or carrion, or they are active predators. Predaceous groups, such as the ground beetles (Carabidae), rove beetles (Staphylinidae), mosquitoes (Culcidae) and various families of biting flies are well-represented in alpine insect faunas, while plant feeding groups, such as leaf beetles (Chrysomelidae), weevils (Curculionidae) and grasshoppers (Orthoptera) are far less diverse here. Alpine terrestrial predators and scavengers rely heavily on allochthonous insects for their food. This topic is discussed by Mani (1968). This exotic food source consists of plants and animals carried aloft by wind onto alpine snowbanks. This includes microscopic food, such as pollen grains and spores, as well as larger plant materials, such as seeds and leaves. Montane and lower elevation insects, spiders and other arthropods are an important food source for scavengers and predators. Many insects take flight on warm summer days, either in search of food or as part of mating behavior. Spiders launch themselves on long strings of silk that catch the wind. Once airborne, these insects and other arthropods are frequently caught in strong upslope winds. When they reach high altitudes, the cold air causes them to fold their wings. Some of these insects land on snowbanks, where their bodies are chilled to the point of immobility and eventual death. Alpine predators and scavengers run out onto the snow to feed on these moribund insects.

One of the more interesting groups of predators operating at high elevations are ground beetles in the genus *Nebria* (Fig. 7). Some species of *Nebria* live near snow banks that persist through the summer months, and at night they hunt other insects that have become trapped on the snow surface. The *Nebria* beetles that live in the alpine zone are physiologically adapted to function at temperatures near freezing, and they have very long legs that help keep their bodies raised off of the surface of the snow, to avoid chilling. Presumably they hunt on snowfields at night to avoid predation by birds.

Arthropods that are active at lower elevations in autumn form another important source of food for alpine scavengers, even though the later are usually forced to enter diapause by early September. Organisms that fall on alpine snowbanks in the autumn remain frozen in the snow until the spring thaw. Then their frozen carcasses thaw out of the snow layers. Some of these are deposited on the ground adjacent to retreating snowbanks, where they provide an important food source for terrestrial predators and scavengers that are just coming out of their winter diapause. Other frozen carcasses form part of the flotsam carried from melting snowbanks into alpine streams and ponds, where they provide food for aquatic predators and scavengers. The top of the food chain on alpine snowbanks includes birds that hunt for insects on the snow surface, as well as predaceous insects, such as ground beetles and rove beetles that hunt the insect scavengers searching for food on the snow.

Selection of Overwintering Sites

All alpine arthropods on land or in shallow waters are exposed to freezing temperatures for much of the year. Nevertheless, even in permafrost areas, insects take shelter under winter snow that insulates them from air temperatures that are far lower. Although alpine ridge tops are typically blown free of snow in winter, good protection beneath snow is available in other alpine habitats, such as snowbanks in depressions and on the lee side of hills. Bottom sediments in alpine ponds are likewise considerably warmer than the air. A study of temperatures beneath snowbanks in Svalbard showed that temperatures beneath just 30 cm of snow remained extremely stable and did not fall below -2°C , even though air temperatures above the snow dropped as low as -24°C (Convey et al., 2015). These stable, near-freezing environments beneath the snow allow some alpine insects and other arthropods to remain active during the winter. Slatyer et al. (2017) studied the sub-nivean arthropod fauna of the Australian alpine region, and found individuals from 18 arthropod orders that were active beneath the snow during winter. These arthropods included springtails (Collembola), spiders (Araneae), mites (Acari) and beetles (Coleoptera). These groups accounted for 95–98% of the individuals collected.

Fig. 7 Photographs of three species of alpine predatory beetles in the genus *Nebria*. Photos courtesy of Mackenzie Flight.

Survival and winter activity beneath the shelter of snow in alpine ecosystems apparently facilitates the multi-year life history of some cold-adapted beetles. Hågvar et al. (2017) studied the ground beetle fauna living beneath winter snow in an alpine region of southern Norway. They documented a two-year life cycle for three common alpine species of ground beetles: *Nebria nivalis*, *N. rufescens*, and *Patrobus septentrionis*. The extended life cycle was facilitated by the simultaneous hibernation of larvae and adults under the snow. Furthermore, both larvae and adults of *P. septentrionis* showed considerable activity through the winter months, beneath the snow. This study indicates that some individuals may hibernate a second time and thus experience two egg-laying seasons. The ability of these beetle species to be active under snow was found to be one of the critical aspects of their ecological requirements.

Paradoxically, warm winters are actually more hazardous for alpine insects than cold ones. Boychuk et al. (2015) point out that repeated freeze–thaw cycles are more common in mountain habitats during unusually warm winters, and that mild winters often lack the significant snowfall levels of colder winters (Fig. 8). Insulation beneath snow cover is especially important in spring and autumn, when early accumulation or late melt of snow cover can extend the period during which environmental temperatures are buffered. In contrast, reduced snow pack exposes overwintering insects to extreme low air temperatures in the spring and autumn, especially because these are seasons when insect cold tolerance may be inadequate for survival.

Some alpine stream insects survive temperatures below freezing as overwintering eggs, including some black flies and mayflies. Some aquatic insect eggs, such as those of the dragonfly genus *Lestes*, survive temperatures below -20°C , and as low as -28°C in *Lestes congener*, although snow cover is also necessary for winter survival (Danks, 2007). In some caddisflies that live in temporary pools, the gelatinous egg matrix resists freezing and drying and perhaps even provides freeze-tolerance to the eggs. However, in frozen streams, the eggs of the stonefly *Arcynopteryx compacta*, although encased in ice, overwinter down to -29°C . This is not accomplished through freezing, but by supercooling through loss of up to two-thirds of the normal water content (see desiccation tolerance, below).

Fig. 8 Flow charts tracing the environmental impacts on alpine insects during cold and warm winters, respectively, based on concepts from Boychuk et al. (2015).

Cold-Temperature Physiology

Alpine insects are able to function at temperatures near freezing because of a set of physiological adaptations. Their body chemistry is geared to function at temperatures near or below freezing. In cold-acclimated beetles, motor nerve fibers show six different activity types, compared with only two types in warm-acclimated beetles. The metabolism of alpine insects in cold temperatures functions at rates similar to those of temperate-zone insects living in moderate temperatures. Cold-adapted insects have evolved 'cold-adapted' enzymes that facilitate chemical reactions at low temperatures (Georlette et al., 2004). Enzymes are organic catalysts, and the package of enzymes in cold-adapted insects have a high catalytic efficiency. However, this efficiency comes at a price: their effectiveness breaks down at higher temperatures. One might be tempted to think that cold-adapted alpine insects would thrive in the kind of warm temperatures experienced at lower elevations, but this is not the case. Because cold-adapted metabolism is facilitated by enzymes that work *only* at low temperatures, alpine insects exposed to temperatures above about 15–20 °C often die because of metabolic failure. Specifically, the weak stability of these enzymes, at even moderate temperatures, causes them to become ineffective and even break down (Georlette et al., 2004). Cold-adapted insects produce enzymes that have a specific activity at low temperatures that is up to tenfold higher than the enzymes in warm-adapted insects. This is the principal physiological adaptation to cold at the enzyme level. It compensates for the otherwise inhibitory effect of low temperatures on chemical reaction rates, providing alpine insects with sufficient metabolic activity to carry out their life cycles in frigid temperatures.

Recent studies have examined the unique aspects of metabolic regulation and cell preservation that facilitate natural cold hardiness. Because cold-hardy insects seek shelter beneath the surface (i.e., underneath snow cover, in frozen mud, under piles of plant debris), their access to atmospheric oxygen becomes limited. Furthermore, insects living in alpine regions survive the winter either in their egg stage, or as overwintering larvae or adults that undergo diapause. Insect metabolism requires oxygen, but because environmental oxygen is limited or unavailable to overwintering insects buried beneath the surface, they must be able to cope

with anoxia. Oxygen requirements fall as insect metabolic rates slow during diapause. Winter survival of cold-adapted insects is enhanced by active suppression of energy-expensive cell functions, including mitochondrial activity. However, survival in oxygen-poor or oxygen-starved environments does not include the suppression of all biochemical functions. There is up-regulation of the hypoxia inducible factor, HIF-1, to coordinate responses that provide hypoxia protection and prevent loss of hemolymph flow to vital organs. This involves increased cellular response to molecular stimulus due to an increase in the number of receptors on the cell surface. Overall, the studies summarized by Storey and Storey (2010) show that cold hardy insect species use a suite of dynamic responses to modulate cellular metabolism in response to seasonal, low temperature, and freeze/thaw cues.

Acclimation and Cooling Rates

The difference between summer and winter temperatures is quite large in many alpine regions. On exposed surfaces, temperatures can vary by as much as 50 °C between seasons. Most alpine insects acclimatize to the cold in the weeks just before winter (Everatt et al., 2015). They prepare themselves physiologically and improve their low temperature tolerance. As autumn progresses, insects use environmental signals such as shortening day lengths and gradually decreasing temperatures to trigger seasonal cold-hardening adaptations. These mechanisms include dramatic changes in biochemistry, cell function and gene expression that permit improved cell function and viability at low temperature (Teets and Denlinger, 2013). Rapid cold hardening mechanisms include dramatic changes in biochemistry, cell function and gene expression that provide improved cell function and viability at low temperature.

The connection between cold-hardiness and gene expression has been investigated for stick insects (Phasmatodea) in New Zealand by Dunning et al. (2013). Of the New Zealand stick insect fauna, only one species of the genus *Micrarchus* is found exclusively at high elevations. This species inhabits the mountain ranges of north-west South Island, which regularly experience sub-zero temperatures throughout the year. All life stages of this species overwinter. Prior to this study, nothing was known about cold tolerance in stick insects. Likewise, very little was known about the genes underpinning their cold tolerance. The authors identified the following about cold-responsive genes.

- (1) The *snd1* gene encodes a complex, six-domain, multifunctional protein with many biological functions. Rapid cold-hardening in *Drosophila* reduces apoptosis and lowers caspase-3-like protein levels, and the authors speculate that elevated expression of *snd1* in the cold-adapted species of *Micrarchus* may be associated with this process. It is possible that *snd1* expression is part of a general stress response in *Micrarchus*, rather than being specifically cold-related.
- (2) Increased expression of the PAHA1 gene in this species of *Micrarchus* might be associated with stabilization or the refolding of proteins that were denatured by cold-shock treatment, or to stabilize structural peptides in anticipation of future cold exposures.

Rapid transitions from summer to winter can leave alpine insects unprepared. If they fail to achieve cold-hardiness in time, the survival of freeze-tolerant species is threatened. Such quick seasonal transitions also raise the supercooling point of freeze-avoiding species, and reduce the capacity of these animals to survive chilling injuries. However, many alpine insects have developed a survival mechanism that allows them to cope with rapid temperature drops. This is called rapid cold hardening. This response allows insects to adjust quickly to falling temperatures within a few days or less. However, relatively little is known about the physiological mechanisms that lie behind rapid cold hardening.

Freeze Tolerance and Freeze Avoidance

Insects have evolved various adaptations to cold, from avoidance of freezing temperatures to tolerance to freezing. These topics are covered in-depth in Denlinger and Lee (2010). The ability to acclimatize to cold conditions is determined by natural selection for cold adaptation. There are two physiological mechanisms by which cold-adapted insects survive freezing temperatures. The first of these is freeze-avoidance; the other is freeze tolerance. Freeze-avoiding insects can be separated into four different groups (Everatt et al., 2015). These include true freeze-avoiding taxa, for which their lower lethal temperature equals the supercooling point. There is also a group of chill-tolerant taxa that show minimal pre-freeze mortality, as well as chill-susceptible taxa that die well above their supercooling points. Finally, there are opportunistic survival taxa that are unable to survive below their developmental threshold.

For small invertebrates, tolerance to temperature extremes is not a necessary adaptation to alpine environments. Instead, the capacity to maintain activity at low temperatures (c. 0 °C) and avoid or tolerate freezing should determine a species' ability to persist in these areas (Mani, 1968). Further, Sinclair et al. (2003) suggested that the mechanisms by which individuals survive sub-zero temperatures are, at least in part, a reflection of the predictability of their environment; freeze tolerance (survival of internal ice formation) predominates in unpredictably cold environments, while freeze avoidance (depression of the freezing point, with ice formation lethal) is more common in predictable, moderately cold environments.

Insects that exhibit resistance to freezing temperatures are able to occupy extremely cold regions. Most cold hardy insects develop freeze avoidance mechanisms because the indiscriminate formation of ice inside the body is lethal. The development of ice nucleators and antifreeze proteins are of critical importance for cold-hardy insect survival in winter. They survive at low temperatures by removing ice nucleating agents from their body fluids that could potentially cause spontaneous internal freezing.

They also accumulate low molecular weight compounds (glycerol or other polyols) in such high concentrations that their bodies remain unfrozen, even at temperatures as low as -40°C to -60°C . Thus, they overwinter in a super-cooled state, stabilized by the production of internal antifreeze compounds. Supercooling is principally achieved via three processes, and is biochemically simpler than freeze tolerance. The first is the removal of ice nucleating agents. Another method of prohibiting ice formation inside freeze-avoiding insects is the accumulation of antifreeze proteins, as well as the production of polyols (organic compounds with multiple hydroxyl groups), sugars and amino acids. Together, these chemical compounds serve both to protect insects from freezing and to enhance their metabolic functions at lower temperatures.

Supercooling points (SCP, nucleation temperature, or crystallization temperature) of insects and other terrestrial arthropods vary greatly, from -2°C to -100°C or lower (Duman et al., 2010). Supercooling is affected by a number of factors, including the volume and water content of the organism, and the ability of the body surface to prevent inoculative freezing by external ice. Freeze-tolerant species often exhibit high SCPs (above -10°C) and have selected for extracellular ice nucleators, while freeze-avoiding insects generally have selected against ice nucleators and for antifreezes, allowing them to supercool below ambient temperatures to which they are exposed over the winter. Protein ice nucleators limit supercooling by organizing water into an ice-like structure, the embryo crystal that promotes freezing at a temperature higher than that where ice would otherwise form. Experiments have shown that this strategy lowers the supercooling point of bodily fluids by up to 20°C in some insects (Everatt et al., 2015).

Freeze-tolerance is another vital survival mechanism for insects subject to long-term exposure to sub-freezing temperatures. This tolerance allows insects to survive through the use of selective internal ice formation. This induced freezing takes place at temperatures just below the freezing point of water (-3° to -10°C) (Everatt et al., 2015), in a controlled manner that minimizes cell damage. Experiments have shown that this strategy lowers the supercooling point of bodily fluids by up to 20°C in some insects. The vast majority of freeze-tolerant insects restrict ice formation to internal body compartments outside their vital organs. This is chiefly done through the accumulation of ice-nucleating agents, including specialized proteins, food particles, crystalloid compounds and even microorganisms. All of these act as locations of water molecule aggregation. By accumulating these agents in the hemolymph (insect blood) and gut, as well as in other tissues, ice formation is encouraged to take place outside of cells. At near-freezing temperatures, ice crystal growth is relatively slow, allowing time for water to be released from cells and join the newly formed ice crystals. Cellular fluids (cytoplasm) therefore become more concentrated and cell walls are less susceptible splitting open because of water freezing inside them.

Freeze-tolerant insects also produce antifreeze proteins and/or antifreeze glycolipids. These compounds stop the expansion of large ice crystals and instead promote the growth of many small crystals that do less damage to tissues. However, these compounds cannot prevent all cellular damage from ice, so freeze-tolerant insects also accumulate additional antifreeze compounds, such as polyhydric alcohols, glycerol, sorbitol and trehalose. Within the cell, these compounds stabilize proteins and membranes, and prevent tissue freezing.

Nevertheless, freeze tolerance poses many challenges to the insect. Freezing can cause cellular dehydration and mechanical damage. As discussed above, existence at temperatures below 0°C greatly inhibits metabolic processes. While freeze-tolerant insects accumulate many potentially protective molecules, the mechanisms underlying freeze tolerance have not yet been fully explored (Toxopeus and Sinclair, 2018). It is thought that freeze-tolerant insects survive the winter by controlling the quality and quantity of ice that forms in their bodies, by preventing or repairing cell damage, by managing biochemical processes while frozen and while thawing, and by restoring their physiological processes after their bodies have thawed (Toxopeus and Sinclair, 2018).

Several species of insects combine both freeze-tolerance and freeze-resistance. Insects of this kind are able to super-cool and at the same time be tolerant to freezing. The molecular basis of this combination of properties remains unknown.

New Zealand has extensive alpine and subalpine habitats where insects are exposed to freezing temperatures. Studies of cold tolerance in New Zealand insects have centered on an alpine Weta (*Hemideina maori*), the world's largest freeze-tolerant insect, and an alpine cockroach (*Celatoblatta quinque maculata*). Both of these insects are moderately freeze-tolerant and have ice nucleating agents in their hemolymph and guts (Wharton, 2011). *H. maori* has been shown to survive with 82% of its body water turning to ice at -5°C . It has been shown that *C. quinque maculata* survives the 28 freeze/thaw events per month that occur during winter in New Zealand's Rock and Pillar Range and that it survives what would appear to be lethal freezing events. The evidence suggests that the lower temperature limit for survival of this cockroach is set by the accumulation of a critical amount of damage in its most sensitive tissues (Wharton, 2011, and references therein).

Alpine insects generally do not feed over winter and hence must rely on stored energy to fuel their metabolism over winter. Most overwintering insects end winter with substantially lower levels of lipids than they had in summer, which suggests that lipids are a primary source of overwintering fuel. Diapause brings on depressed metabolic rates over winter, so the consumption of lipids is more likely to take place in the autumn and spring, when temperatures are higher but insects remain dormant. For freeze-tolerant insects (which withstand internal ice), Sinclair and Marshall (2018) speculate that impaired oxygen delivery limits lipid oxidation when ice forms inside insect exoskeletons. Acetylated triacylglycerols remain liquid at low temperatures and interact with water molecules, suggesting a possible role in cryoprotection. Similarly, antifreeze glycolipids may play an important role in structuring water and ice during overwintering. Lipids are certainly an important component of insect overwintering energetics, but this aspect of insect physiology remains poorly understood.

Desiccation Tolerance

An ability to tolerate water loss is crucial for the survival of some alpine insects, although this adaptation is more commonly found in polar insects. Anti-desiccation adaptations have a good deal in common with freeze-avoidance, including the production of polyols and sugars. Soil-dwelling insects and many immature stages of above-ground species spend most of their time in the soil. These must cope with soil ice during winter. Most of these insects have only two options for survival: either tolerate internal freezing or dehydrate. In frozen soil, there is a strong tendency for ice outside the insects' bodies to draw the liquid water out of their bodies, causing desiccation of tissues (Holmstrup, 2015). A cold tolerance mechanism that retards this process is called cryoprotective dehydration (CPD). Utilization of this protective mechanism requires an insect to withstand substantial dehydration of its bodily fluids. However, CPD is essentially a freeze-avoidance strategy, and the associated physiological traits are essentially the same as those found in freeze tolerance. Dehydration virtually eliminates the risk of tissue ice formation, ensuring survival in frozen soils. Thus, winter survival of soil-dwelling invertebrates depends more on dehydration than on supercooling. However, cryoprotective dehydration can be slow, so some supercooling capacity is needed in its initial phases (Sørensen and Holmstrup, 2011).

Conclusions

The ability of insects to live in extremely cold alpine environments is truly remarkable, and involves every aspect of their lives, from timing of events in their annual life cycles to their behavior patterns and their internal physiology. Most of these adaptations are encoded in their DNA, and geneticists are only now starting to unravel the location and function of genes that control the processes described in this article. In the vernacular, we would say that alpine insects are *hard wired* to live where they do. However, these very adaptations to cold make alpine insects and other invertebrates extremely vulnerable to global warming. As temperatures rise, the native alpine fauna will suffer and decline. As they are already living at such high elevations, there are no higher elevations available for immigration. The rising temperatures will cause decreased fitness in cold-hardy insects, and they will also be forced to compete with more warm-adapted insects, invading from lower elevations. Likewise, changes in the composition of high altitude plant communities, a phenomenon already documented in many alpine regions, will disturb the balance of alpine ecosystems, including long-established plant-insect interactions. The cold-hardiness of alpine insects, their greatest asset for survival in previous millennia, may very well become their greatest liability in the coming decades.

Abstract

Alpine insects are a remarkable group of organisms, not just surviving the frigid climates and short summers of the alpine zone, but actually thriving there. They do this through a series of physiological and behavioral adaptations. These cold-adaptations make it virtually impossible for alpine-dwelling insects to migrate out of their mountain top habitat islands today. However, the DNA, modern and fossil evidence show us that alpine insects have shifted their distributions in the past. The cold glacial periods of the Pleistocene offered these insects the opportunity to disperse into lowland regions. The Pleistocene glacial intervals were times of massive population expansion of cold-adapted insects, down from the mountain tops and out into the periglacial environments of the lowland regions that existed in reasonably close proximity to continental ice sheets and mountain glacial systems.

Introduction

To the casual observer, the sight of insects on mountain tops on a summer's day may seem serendipitous. Indeed, it might seem that these insects were carried upslope by the almost-constant winds of the alpine zone, and that they are doomed to expire when the first cold snap hits the high country. However, a more systematic study of alpine insects reveals that most of them are permanent residents there, not accidental transplants. As are their counterparts in the Polar Regions, these insects are highly adapted to cold temperatures and a short growing season. Alpine insect adaptations are discussed elsewhere in this volume. The point of this article is to review what is known about the distribution of alpine insects, past and present.

Just as in the Arctic, alpine-zone insects are dominated by predators and scavengers. Plant productivity is generally low in these regions. In the alpine, soils are shallow and poorly developed, temperatures are cold, and the growing season is quite short. These factors limit plant productivity and the diversity and abundance of alpine phytophages. Unlike the Arctic fauna, many alpine predators and scavengers rely on arthropod prey (mainly spiders and flying insects) that are transported up to the alpine zone from the mountain forests, below. Many montane and subalpine insects are caught in upslope winds on summer days, and end up on alpine snowfields, where they die of hypothermia. These dead and dying insects form the principal prey for various alpine insects, especially predatory beetles.

The diversity of Arctic insects decreases with latitude, so that the low Arctic has far more diversity of species than polar desert regions of the far north. So also does the diversity and abundance of alpine insects regions decrease with elevation. This is partly due to differences in the richness of vegetation. Lower alpine slopes tend to be gentler than high alpine slopes, which are often steep. The former landscapes tend to have richer, better developed soils that support a greater variety and abundance of alpine vegetation. The latter landscapes range from poorly vegetated to bare rock surfaces and snowfields. The insect diversity of alpine meadows is thus greater than the diversity of rocky peaks (Table 1).

There is a high degree of endemism in alpine insect species. Endemism refers to a species that is restricted to a particular geographic region as a result of factors such as isolation or in response to abiotic conditions. In the case of alpine insects, both conditions apply, i.e., species living in the alpine are geographically isolated from species in other regions, and they are highly adapted to the rather severe abiotic conditions of cold climate, short growing season, high winds, rocky substrates, and other abiotic factors. Mani (1968) has documented the percentage of endemic species in the major orders of Himalayan insects, as follows: Hemiptera—65%; Coleoptera—60%; Hymenoptera—47%; Lepidoptera (butterflies only)—45%. Thus the overall average for all groups is 54% endemic species. Such an accounting has not been done for other mountain ranges, but the proportion of endemics is probably somewhat similar.

Attempts to reconstruct the origins and past movements of alpine insects that are based solely on their modern distributions are like trying to understand a very lengthy novel by reading only the final page. Human lifetimes are simply too short to allow us to observe distributional shifts of organisms at any meaningful timescale. For instance, some cold-adapted insect species have populations both in the Arctic and in alpine regions further south. Presumably at some time in the past there was an original population of such species, but where did that species originate—in the Arctic or on top of some mid-latitude mountain range? Moreover, when did such cold-adapted species arise, and what have been their distributional shifts through time? Biogeographic and genetic studies suggest that dispersal, rather than ecological divergence from low elevation species, is the principal factor governing the biogeography of alpine species (Schoville and Rovito, 2019). Since these dispersal events must have taken place during the Pleistocene, we

must look to the fossil record to piece together the history of alpine insect biogeographic patterns. The modern insect data cannot answer these questions, although the analysis of modern and ancient DNA is starting to shed new light.

Since about the 1930s, zoogeographers have discussed the means by which alpine insects and other organisms survived Pleistocene glaciations—times when their modern mountaintop habitats were generally glaciated. Specifically, it has long been debated whether high alpine taxa survived ice ages in situ on small ice-free islands of habitat, called nunataks, or whether survival during glaciations was restricted to regions of lower elevation, so called “massifs de refuge” that existed beyond glacial limits.

As Mani (1968) noted, the ecological specializations that characterize alpine insects severely restrict their means of dispersal from one mountain range to another. As discussed below, it appears that the cold climates associated with Pleistocene glaciations played a dominant role in the dispersal of these insects across the lowlands that separate mountain ranges. Today these lowlands are far too hot in the summer to be crossed by the extremely cold-adapted insects that live in alpine habitats. These insects are nearly all inactive during winter (another cold-region adaptation), so their potential dispersal is limited to the summer season. Furthermore, many alpine insect species are brachypterous—they lack usable flight wings. There are several reasons why brachyptery is an advantage to alpine insects. First, the alpine regions are some of the windiest regions of the world, often experiencing hurricane-force winds. In such conditions, wings are a handicap, not an advantage. Alpine insects live on patches of treeless mountaintops, surrounded by montane forests. From an ecological perspective, the alpine regions are considered habitat “islands,” surrounded by a “sea” of lower-elevation forests, where alpine insects do not belong. The flightless habit of alpine insects keeps them from being blown off the mountain tops, down to lower elevations. The exception to this is the alpine butterflies and moths (Lepidoptera) and the flies (Diptera). But even these insects that are capable of flight are not adapted to spend the weeks or months that it might take them to traverse inhospitable lowland regions, on their way to new alpine regions. Most of the alpine Lepidoptera species rely on specific host plants for nectar. Many of these plants are found only in the alpine regions.

DNA Evidence

A study of the modern DNA of populations of the cold-adapted ground beetle *Amara alpina* has helped elucidate its Pleistocene history in North America. This species currently has populations throughout the North American Arctic, Greenland, northern Siberia,

the Rocky Mountains and the northern Appalachians. Reiss et al. (1999) analyzed mitochondrial DNA from 22 North American populations of *A. alpina*. They found that populations from Alaska and the Yukon (the former region of Eastern Beringia that was a refuge for Arctic biota in the Pleistocene) were the most genetically diverse, which agrees with the idea that this region was continuously inhabited by this species throughout the Pleistocene. Canadian Arctic regions east of Beringia were colonized by populations from Beringia, but only after the last deglaciation, which took place in arctic Canada only about 6000 years ago. The genotypes of these more eastern Arctic populations are a subset of the Beringian types. Finally, at least two ancestral haplotypes existed in the populations living in the southern refugium from which the Rockies and Appalachian populations were founded. The fossil record of *A. alpina* from the lower 48 states of the United States includes populations living near the margins of continental ice sheets during the Last glaciation. The more westerly of these populations managed to survive postglacial warming of the lowlands by shifting to the alpine zone of the Rockies. The more easterly of these populations managed to survive postglacial warming of the lowlands by shifting to the alpine zone of the northern Appalachians, such as Mount Washington, New Hampshire, and Katahdin, Maine.

DNA evidence from a different region has also dealt a blow to the nunatak hypothesis. This comes from a study of modern ground beetles in the Alps. Lohse et al. (2010) studied the local radiation of high alpine carabid beetles (genus *Trechus*) in the Orobanchian Alps, Northern Italy. Geologic evidence indicates that the summits along the northern flank of this mountain range were surrounded by an ice sheet, leaving the highest peaks as nunataks during the Last Glacial Maximum (LGM), and that the southern flanks of the range remained unglaciated. Lohse et al. analyzed both MtDNA and nuclear DNA samples from 12 beetle populations. They estimated the ancestral location states in the gene trees, which in turn were used to infer the most likely order of recolonization under a model of sequential founder events from a *massif de refuge* from the mitochondrial data. They found that only three of the *Trechus* populations presented genetic evidence that was incompatible with LGM survival in a *massif de refuge*, and that both mitochondrial and nuclear data support separate refugial origins for populations on the western and eastern ends of the northern ridge. Finally, the mitochondrial evidence suggests the persistence of *Trechus* populations on the northern ridge for part of the last ice age.

A study of the mitochondrial DNA (MtDNA) of the alpine butterflies in the *Parnassius phoebus* complex by Todisco et al. (2012) provides fascinating insights into the Pleistocene and Holocene history of these cold-adapted insects. This species complex is unique in the genus *Parnassius* because of its Holarctic distribution. Scattered populations occur in high elevations of the Alps, the northern Urals and in central and eastern Siberia, as well as on mountaintops of western North America from Alaska to California and Colorado (Fig. 1). Butterfly taxonomists recognize five species in this group (Fig. 2), based on their external morphology, ecological requirements, and geographic isolation.

The genetic evidence suggests that there are two distinct clades within this group of butterflies: a North American clade and a Eurasian-Alaskan clade. A clade is by definition monophyletic, including one ancestor and all its descendants. Based on the MtDNA evidence, the estimated time to the most recent common ancestor of the North American clade was less than 125,000 years ago (125 ka). The estimated time to the most recent common ancestor of the Eurasian-Alaskan clade was less than 80 ka. [Todisco et al. \(2012\)](#) argue that the mtDNA data are consistent with range expansions across each of the two continents during the Last glaciation (ca. 30,000–11,000 years ago). They also concluded that significant gene flow between the various populations ended during the Holocene. The authors proposed that this *Parnassius* species complex may serve as a model for Holarctic alpine invertebrates that have moderate dispersal abilities in that its genetic structure at a continental scale reflects extensive connectivity during the most recent glaciation. Butterflies leave essentially no fossil record, except for the occasional caterpillar mandible. However, the fossil beetle record supports this butterfly genetic model of alpine insect distribution pattern. While the modern populations of alpine beetle species are restricted to isolated habitat islands on mountaintops, their Late Pleistocene fossil record demonstrates that they spread throughout many lowland regions during glacial times. This promoted the extensive genetic connectivity—mixing of the gene pools of today's alpine species during lengthy glacial intervals.

Another phenomenon indicated by the *Parnassius* butterfly MtDNA study is that samples of *P. smintheus* from Yukon and British Columbia share their haplotypes with samples from the northern United States (Washington and Montana). This indicates that this species expanded northwards following the retreat of glaciers after the LGM, starting about 19,000 years ago. The North American ice sheets therefore acted as a massive geographical barrier between *P. smintheus* and *P. phoebus* during the last glacial period. This

phenomenon has also been observed in the fossil beetle record from the lower 48 states of the United States. As discussed below, populations of cold-adapted beetles lived at low elevations south of the Laurentide and Cordilleran Ice Sheets during the Last glaciation. These ice sheets formed an insurmountable physical barrier between arctic and mid-latitude populations of many cold-adapted species. When deglaciation began, some species were able to disperse northward along the edge of the retreating ice. However, most cold-adapted species either retreated to mountain-top regions as they became ice-free, or if this mode of dispersal was geographically untenable, then some species simply were extirpated from the middle latitudes of North America. These postglacial mountain refuges include the alpine zones of the Sierras, Cascades, Rockies, and northern Appalachians. The Rocky Mountains have the best-documented Late Pleistocene and Holocene insect fossil record, so they form the basis of much of what follows.

Fossil Beetle Evidence—North America

The mountain tops of the Rockies form an archipelago of alpine habitat islands, stretching from the Arctic tundra of Canada south to the highlands of New Mexico. As such, these habitat islands have provided a series of migration corridors for cold-adapted biota, with the Great Plains on the east and various deserts and other arid regions on the west. As shown in Fig. 3, the most mountainous state of the Rockies, Colorado, has hundreds of relatively small alpine patches, many of which are isolated from other patches by 20 km or more. However, during the last glaciation, the alpine zone expanded downslope to about 3000 m elevation, covering what is now subalpine forest. The dark green areas seen on the map represent the current subalpine zone, but during the last glaciation those forests likewise shifted downslope by around 1000 m. Much of the expanded alpine regions were glaciated during the LGM, but the Southern Rockies were too dry to support many large glaciers. Thus the available alpine habitat for cold-adapted insects expanded during the last glaciation. As predicted by the butterfly MtDNA results, populations of alpine insects in the Rockies that had previously been isolated from each other during interglacial warm periods would have been able to spread into much larger areas during glacial cold periods, as their alpine habitat expanded.

Thousands of analyzed Quaternary beetle assemblages (summarized in Elias, 2010) have demonstrated that beetles (and probably many other groups of insects that lack substantial fossil records) shift their geographic ranges in response to climatic oscillations. Evidence for large-scale range shifts of this kind has been found in fossil assemblages from Europe (Coope, 1973), Australia (Porch et al., 2009), New Zealand (Marra, 2003), and North America (Elias, 1991). There is scant fossil evidence of insect extinctions due to Pleistocene glaciations, even in the more sedentary insect groups (Coope, 1978). In the Arctic, where permafrost deposits have yielded insect exoskeletal fossil assemblages dating back to the Pliocene, the vast majority of identified species represent extant taxa (Elias and Matthews, 2002).

Fig. 3 Map of the current alpine zone in Colorado (*white areas*) and the presumed extent of the alpine and glaciated zone in Colorado during the LGM (*dark green areas*).

The last 2.6 million years (the Quaternary) represent an interval of time during which climates of the temperate and high latitudes have oscillated frequently, and on large scales. Insect migrations in response to these climatic oscillations have not been deliberate acts to move away from unsuitable environments. Rather, as typical r-selected biota, insects generally have large numbers of offspring, and most of these offspring move away from their point of origin, to minimize competition with other members of the local population. This habit of fanning out in all directions ensures that species survive environmental changes, climatic, and otherwise. Those individuals that happen to migrate to regions that still fall within the suitable environmental envelope of their species will survive such changes. Even if only a small percentage of a population lands in a suitable habitat, their rapid reproduction and large numbers of offspring ensure that the species itself survives the environmental change. Over Quaternary time scales, this phenomenon has made virtual globe-trotters of some beetle species (Elias, 2015).

The Rocky Mountains are an ideal region to test the competing hypotheses on the regional survival of alpine insects during glaciations, for two reasons. First, the chain of Rocky Mountain ranges extends from the edge of the Arctic tundra in Canada to the edge of the Chihuahuan Desert in New Mexico, facilitating comparisons along a 4800 km corridor of highlands. Second, organic deposits from sites in the Rockies and from adjacent lowland areas have provided good fossil evidence of the distributional shifts of beetles in response to Late Pleistocene glaciation.

The author has studied 122 fossil insect assemblages from 13 sites, ranging from northern Montana to southern Colorado (Elias, 2015). More than 90% of the identifiable fragments of insect exoskeleton preserved in these organic deposits come from beetles, or Coleoptera. Beetles are the largest order of insects, and their exoskeletons are more heavily reinforced with chitin than those of most other insect orders. The results of these studies reveal a variety of insect responses to the last glaciation.

Roughly three-quarters of the 200 beetle species identified from the Rocky Mountain regional faunal assemblages apparently remained in this region during the Last glaciation. It appears that nearly all these species shifted their ranges downslope, thereby escaping mountain glaciers. Thus far we have found no fossil evidence for survival of any beetle species on nunataks—bare peaks that rose above regional glaciers and ice sheets in the Rockies. The other 45 species (23%) found in Rockies fossil assemblages have become regionally extirpated. In other words, they are apparently no longer resident in this region, although they persist elsewhere. None of the 200 species in the fossil assemblages has gone extinct. Roughly half of the extirpated species found in fossil assemblages from the LGM are found today in either the arctic or the boreo-arctic regions of Canada and Alaska.

The oldest fauna discussed here, dated to the LGM (21,700 year BP), is from the Lamb Spring site, situated in the foothills west of Denver, Colorado. This fauna included the regionally extirpated species of water scavenger beetle *Helophorus splendidus*. This species is found today only along the shores of the Arctic Ocean of Canada, west of Hudson Bay (Fig. 4). The populations that lived south of the Laurentide and Cordilleran Ice Sheets may have died out completely toward the end of the last glaciation. If that is the case, then the modern Arctic populations may be derived from populations that survived the LGM in Eastern Beringia—the unglaciated lowlands of Alaska and the Yukon. However, the lack of any known modern populations in the Beringian region strongly suggests that small populations of *H. splendidus* followed the retreating margins of the continental ice sheets as they moved northward through the last 18,000 years. Based on the climatic conditions at the modern collecting localities for *H. splendidus*, it is adapted to live where mean July temperatures (Tmax) are 8°C–10°C, and where mean January temperatures (Tmin) are –34°C to –28°C. This means that this beetle is adapted to the extremely cold temperatures found only in Arctic and alpine regions today.

This scenario of beetle populations following the retreating margins of ice sheets has also been suggested for the postglacial history of another member of this genus, *Helophorus arcticus* (Morgan, 1989). Interestingly, this LGM fauna from Lamb Spring contains several species of beetles now found in the alpine regions of Colorado. This strongly suggests that alpine insects shifted downslope during the Last glaciation, which supports the *massif de refuge* hypothesis over the nunatak hypothesis.

Fig. 4 Modern distribution of the cold-adapted water scavenger beetle *Helophorus splendidus*. Inset: photo of *H. splendidus*, courtesy of Creative Commons.

The younger of the two faunas from Lamb Spring, directly dated to 17,600 year BP, includes the rove beetles *Olophrum rotundicolle*, *Tachinus elongatus*, and *Gymnusa atra*. *Olophrum rotundicolle* is a boreo-arctic species that ranges south along the Appalachian chain but is not known from the Rocky Mountains today (Campbell, 1983). It was found in fossil assemblages from the Colorado Rockies that are as young as the last thousand years but is apparently not present in the Rocky Mountain region today. *Tachinus elongatus* is a boreo-montane species, with modern populations extending south along the Rocky Mountains to the Medicine Bow Mountains of southern Wyoming (Campbell, 1973). The southern edge of its modern range is only about 100–200 km north of the sites from which it has been found in Colorado. It persisted in Colorado until at least 2000 years ago; its last fossil record is from a site in Rocky Mountain National Park.

The Late Glacial interval began about 17,000 year BP in the Rocky Mountains, and ended about 11,600 year BP. By that time, the margins of mountain glaciers and ice caps were rapidly retreating upslope, exposing subalpine and then alpine landscapes for the first time in about 18,000 years. Not surprisingly, the trees of the subalpine forest did not become established at the modern treeline elevations until about 1500 years later, as soil development and primary succession had to take place before the trees could reach their elevational limits (Elias, 1985).

The extirpated species found in Late Glacial beetle faunas from the Rockies include the ground beetle *Bembidion sulcipenne hyperboroides*, the carrion beetle *Thanatophilus trituberculatus*, the water scavenger beetles *Helophorus alternatus*, *H. sempervarians*, and *H. splendidus*, the rove beetles *Olophrum boreale*, *O. rotundicolle*, *Stenus hyperboreus*, and *Holoboreaphilus nordenskiöldi* (Fig. 5). *Bembidion sulcipenne hyperboroides* is known today only from the boreo-arctic regions of northwest Canada and Alaska (Lindroth, 1963). It was found in the faunal assemblage from Marias Pass, Montana, dated at 13,400 year BP. This locality is about 1800 km southeast of the southern limit of its modern range in northern British Columbia. The carrion beetle *Thanatophilus trituberculatus* was also found in this assemblage, and is likewise found today only in the boreo-arctic regions of North America (Anderson and Peck, 1985). The rove beetles *Stenus hyperboreus* and *Holoboreaphilus nordenskiöldi* are both cold-adapted species. The former species is found today in the boreo-arctic regions of North America. It was part of the 15,000-year old fauna from a site in the central Colorado Rockies. *Holoboreaphilus nordenskiöldi* is an arctic species today. Its modern range includes the arctic coastal regions of North America and Siberia, as well as alpine tundra localities in Alaska and the Yukon (Campbell, 1978). This species was also part of the Late Glacial assemblage from Marias Pass, Montana.

The water scavenger beetles discussed above have very different modern distributions. *Helophorus alternatus* is found today only in the highlands of California and Oregon (Smetana, 1985). This species was found in central Colorado Rockies assemblages ranging from 16,000–15,000 year BP. On the other hand, *Helophorus sempervarians* is a boreo-arctic species today, with no known populations in the western United States. Finally, *Helophorus splendidus* is an arctic species, as discussed above. Its youngest occurrence in Rocky Mountain fossil assemblages also comes from the 15,000-year old assemblage in the Colorado Rockies.

Fig. 5 Rocky Mountain beetle species extirpation chronology since the Last glaciation.

The modern ranges of the regionally extirpated species found in Late Glacial faunas from the Rockies are mostly in the arctic and boreo-arctic regions (Table 2). However, about a quarter of the species are found today only in the Pacific Northwest (PNW) region, with the remainder being found today either in the alpine regions of the mountain ranges of New England (i.e., the Presidential Range of New Hampshire and Mt. Katahdin, Maine), or in the Northern Rockies. Interestingly, while the migration corridors between the Rockies and the PNW region remained open for beetles after the Late Glacial interval, migration between eastern North America and the Rockies appears to have stopped in the early Holocene, about 11,000 years ago.

The early Holocene interval is taken here to mean 11,500–5000 years ago. The extirpated species found in early Holocene beetle faunas from the Rockies include the ground beetles *Bembidion rusticum lenensoides* and *B. sierricola*, and the rove beetles *Phlaeopterus longipalpus* and *Stenus sibiricus*. *Bembidion rusticum lenensoides* is found today in the western boreo-arctic region, much like *B. sulcipenne hyperboroides*. It was found in a fossil assemblage dated 9000 year BP from the San Juan Mountains of southern Colorado. *Bembidion sierricola* is known today only from the mountain ranges of the Pacific coast. Its last appearance in Rocky Mountain fossil assemblages was also at 9000 cal years BP in Southern Colorado. Unfortunately, no fossil beetle research has been carried out in any California highlands, so we know nothing of the beetle faunal history of this region.

The rove beetle *Phlaeopterus longipalpus* is an alpine snowfield species, known today from the high mountains of the PNW region, extending southeast to Utah (Hatch, 1957). It was found in fossil assemblages from a high-altitude site in northern Colorado, in assemblages ranging from 10,000–1500 year BP. Thus, it would seem that its extirpation from the Southern Rockies has been quite recent. *Stenus sibiricus* is known today only from the Arctic (Campbell and Davies, 1991). Its fossil remains were found in a sequence of assemblages ranging from 11,000–9000 years old from a high-altitude site in central Colorado.

Table 2 Modern and Late Pleistocene ranges of alpine beetle species from North America

Species	Modern North American range	Late Pleistocene records
Family Carabidae		
<i>Carabus taedatus</i>	Arctic; alpine of western mountains	Wisconsin, Minnesota: Late glacial; AB: Late Holocene
<i>Nebria arkansana</i>	Alpine of the Rocky Mountains	Colorado: Mid-Holocene
<i>Nebria gyllenhali</i>	Arctic; alpine of eastern and western mountains	Alberta: Late Holocene
<i>Pterostichus pinguedineus</i>	Arctic; alpine of eastern mountains	Pennsylvania: Late glacial
<i>Pterostichus surgens</i>	Alpine of the Rocky Mountains	Colorado: LGM, Early Holocene
<i>Stereocerus haematopus</i>	Arctic; alpine of Eastern mountains and Wyoming	Quebec: Late glacial
<i>Amara alpina</i>	Arctic; alpine of eastern and western mountains	Quebec: Late glacial; Colorado: Late glacial and Early Holocene
<i>Trichocellus cognatus</i>	Arctic; alpine of eastern and western mountains	Quebec: Early Holocene
<i>Trichocellus mannerheimi</i>	Arctic; alpine of Colorado	Colorado: Early to mid-Holocene
<i>Cymindis unicolor</i>	Alpine of eastern and western mountains	Wisconsin: Late glacial; Minnesota: Late glacial; Quebec: Late glacial; Michigan: Late glacial
Family Staphylinidae		
<i>Tachinus angustatus</i>	Alpine of western mountains	Colorado: MIS5b
<i>Tachinus elongatus</i>	Boreo-arctic; alpine of Colorado, New Hampshire, Wyoming	Pennsylvania: LGM; Quebec: Early Holocene; Colorado: MIS 5c and 5b, Late glacial and Early Holocene
<i>Tachyporus nimicola</i>	Alpine of New Hampshire, New York, Colorado	Colorado: MIS 5b and 5c, Early Holocene
<i>Phlaeopterus filicornis</i>	Alpine of Sierra Nevada	Colorado: Early and mid-Holocene
<i>Acidota quadrata</i>	Arctic; alpine of New Hampshire, Colorado, Montana	Wisconsin: Late glacial; Ontario: Early Holocene; Pennsylvania: LGM and Late glacial; North Dakota: Early Holocene; Colorado: Early Holocene, mid-Holocene and Late Holocene
<i>Olophrum boreale</i>	Boreo-arctic; alpine of Montana, Wyoming, Utah	New York: Early Holocene; Pennsylvania: Early Holocene; Ontario: Late glacial; North Dakota: Early Holocene; Colorado: MIS 5a, Late glacial and Early Holocene; Washington: MIS 3, MIS 2
<i>Olophrum rotundicollis</i>	Boreo-arctic; alpine of Colorado	Nova Scotia: Late glacial; New York: Late glacial and Early Holocene; North Dakota: Early Holocene; Minnesota: Late glacial; Ontario: Late glacial; Colorado: Late glacial, Early and Late Holocene
<i>Eucnecusum brachypterum</i>	Arctic; alpine of eastern mountains	New York: Late glacial and Early Holocene; Colorado: MIS 5a and 5c
<i>Eucnecusum tenue</i>	Boreo-arctic; alpine of Colorado, Utah	Wisconsin: Late glacial; North Dakota: Early Holocene; New York: Late glacial; Ontario: Late glacial; Colorado: MIS 5a, Early and Late Holocene
<i>Eucnecusum brunescens</i>	Boreo-arctic; alpine of Colorado	Ontario: Late glacial; Colorado: MIS 5a, Late glacial, Early Holocene, Mid-Holocene and Late Holocene
Family Silphidae		
<i>Thanatophilus coloradensis</i>	Boreo-alpine in the Rocky Mountains, British Columbia	Colorado: MIS 5e and 5b

The latter half of the Holocene saw climatic cooling in the Rocky Mountain region, especially in the last 3000 years, when both summer and winter temperature averages dropped below modern levels (Elias, 1996). *Bembidion striola* is confined today to the Pacific coastal mountain ranges (Lindroth, 1963). Its last known occurrence in the Rockies was at 2000 year BP at a site in Rocky Mountain National Park (RMNP), Colorado. The last known occurrence of *Oxytelus montanus* was at 2000 year BP, also in RMNP. This species is found today in the PNW region. Perhaps the most surprising aspect of the late Holocene faunas is that so many species were extirpated so recently from the Rockies. Of the 45 species known to have been extirpated from this region in the last 125,000 years, eight died out regionally within the last few thousand years. This speaks to the dynamism of insect migration. Each species is constantly attempting to become established in new regions. There are no stable insect communities, in any meaningful sense of the term. Perhaps the factor driving the disappearance of so many species from the Southern Rockies to the PNW region was a change in precipitation. If the extirpated species are adapted to wetter climatic conditions than those available in the Southern Rockies today, then only their PNW populations would have survived, as the PNW region is considerably wetter than the Southern Rockies.

A number of cold-adapted beetle species that live today in the alpine regions of the northern Appalachian Mountains, such as the Presidential Range in New England and Mount Katahdin in Maine, have Late Pleistocene fossil records from lowland regions of eastern and central North America. For instance, the ground beetle *Pterostichus pinguedineus* is known today from the Arctic and from the alpine of the northern Appalachians, but fossil specimens have been identified from a lowland site in Pennsylvania, dating to the Late glacial interval. It would appear that eastern lowland populations retreated to the northern Appalachians at the beginning of the Holocene. Likewise the rove beetle *Eucnecusum brachypterum*, a species commonly found in fossil assemblages from cold intervals in Europe and North America, has a modern North American distribution limited to the Arctic, and to the alpine zone of the northern Appalachians. Its relative, *Eucnecusum brunnescens*, is another cold adapted species. Fossils have been found that date to the Late glacial interval in southern Ontario and to the both the Late glacial and Holocene in Colorado. Today it is found in the Colorado alpine and in the boreo-arctic regions of North America. Presumably the populations that lived just south of the Laurentide Ice Sheet in Ontario migrated north as the ice margin retreated, becoming established in the cold boreo-arctic regions of Canada during the Holocene. Similarly, *Eucnecusum tenue* lived during the Last glaciation in regions south of the Laurentide Ice Sheet, as attested by fossil localities in Wisconsin, North Dakota and New York. It also lived in the Rocky Mountain region, downslope from mountain glaciers during the Last glaciation. The mid-western and eastern glacial populations presumably followed the retreating margins of the Laurentide Ice Sheet, and have become established in the boreo-arctic regions of Canada during the Holocene. The glacial-age populations in Colorado migrated upslope to the alpine zone in the Holocene.

Fossil Beetle Evidence—Europe

A similar story of alpine insect advances and retreats in the face of glacial-interglacial cycles can be seen in the fossil beetle record from sites in Europe. Quite a number of these cold-adapted beetle species live today either in the Arctic, or in both the Arctic and alpine regions of Europe. But the Late Pleistocene fossil record of these species clearly demonstrates that they came down out of the high mountains of Europe, and onto the adjacent lowlands during glacial intervals. Such beetle species were the dominant elements in glacial-age assemblages from Britain, the Netherlands, Germany, France, and other countries in Europe. For example, *Diacheila polita* is an arctic ground beetle with a Holarctic distribution today. Fossils of this species have been commonly found in British fossil records as well as in glacial assemblages from Eastern Europe and in North America, south of the last glacial ice sheets. In modern Eurasia, *D. polita* is found only in arctic regions from the Kola Peninsula eastward. In North America, it is found today only in arctic and subarctic regions of Alaska and the Yukon Territory, with isolated populations on alpine tundra in the Alaska Range.

As discussed above, *Amara alpina* is an arctic and alpine species today, with populations extending south along mountains in Scandinavia. It is the northernmost ground beetle in the Arctic fauna, ranging north to northernmost Greenland, Ellesmere Island in Canada, and northernmost Siberia. Fossils of *A. alpina* have been found in several European lowland sites from cold-interval assemblages. Interestingly, this species was present as far south as northern Italy during the Last glaciation, but it does not inhabit the Alps today. The most likely reason for this is that *A. alpina* is both cold-adapted and dry-adapted, and the climate of the Alps is probably too wet for this species.

An alpine water beetle, *Helophorus glacialis*, was found in Swedish, British, French, and Swiss lowland fossil assemblages from the Last glaciation. Today this species is confined to mountain top ponds in the Pyrenees, Alps, Scandinavian Alps, and some isolated mountain tops in smaller mountain ranges of Europe. Another cold-adapted species of this genus, *Helophorus lapponicus*, was widespread in Western Europe during the cold phases of the last glaciation, but its modern distribution reflects the species' retreat to the northern regions in Scandinavia and mountainous regions as far south as Spain. Angus (1983) captured modern specimens of this species from Sweden and Spain. He brought them into his laboratory and observed that the two populations successfully interbred, despite their genetic isolation of the two populations during the last 11,000 years.

The pill beetle (Byrrhidae), *Syncalyptra cyclolepidia* apparently lived throughout much of lowland Europe during the last glaciation. It has been found in British fossil faunas as well as from glacial-age assemblages near the end of the last glaciation in northern Switzerland. Today this moss-feeding beetle occupies arctic and alpine regions of Scandinavia, and has isolated populations in the Alps of Austria. Why did it not also relocate to the highlands of the Swiss Alps? We will probably never know the answer, but its

Fig. 6 Modern European distributions of *Syncalyptra cyclolepidia* and *Helophorus glacialis*.

absence from modern day Switzerland demonstrates the somewhat serendipitous nature of insect species migration in response to rapid, large-scale climate change. No species operates in a vacuum. Perhaps other species of pill beetles that lived within reasonable proximity to the Alps toward the end of the Last glaciation had a slight competitive advantage over *S. cyclolepidia*. A checklist of Swiss Coleoptera lists five species of Byrrhidae currently living there. The pill beetle species that lives at high altitude is *Byrrhus pilula*. Like *S. cyclolepidia* (and almost all other Byrrhidae), *B. pilula* feeds on mosses. According to the fossil record, from 125,000–12,000 years ago, *B. pilula* lived in England. But this species has a much broader thermal tolerance than *S. cyclolepidia*. *B. pilula* can be found today in mossy habitats from sea level to the snowfields of the Alps. Perhaps its broad thermal tolerance gave it a competitive advantage over *S. cyclolepidia* at the end of the Last glaciation.

The water scavenger beetle *Helophorus glacialis* was likewise widespread on periglacial landscapes of the European lowlands during the Last glaciation. But unlike *S. cyclolepidia*, *H. glacialis* managed to become established in many of the alpine regions of Europe, from the Pyrenees and Alps to the Tatra and Carpathian Mountains of Central Europe, and south to the Pindus Mountains of Greece (Fig. 6).

Conclusions

Alpine insects are a remarkable group of organisms, not just surviving the frigid climates and short summers of the alpine zone, but actually thriving there. They do this through a series of physiological and behavioral adaptations. This package of cold-adaptations makes it virtually impossible for nearly all alpine-dwelling insects to migrate out of their mountain top habitat islands in an attempt to colonize other alpine regions. However, the DNA, modern and fossil evidence combine to show us that alpine insects have shifted their distributions in the past. The fossil evidence clearly indicates that the cold glacial periods of the Pleistocene offered these insects the opportunity to disperse into lowland regions, where they survived in what must have been far larger populations than those of today on mountain top habitat islands. From the standpoint of cold-adapted insect biogeography, the current and previous warm interglacial periods have been times of population decline and forced retreat to mountain tops. In contrast to this, the glacial intervals of the Pleistocene were times of massive population expansion, down from the mountain tops and out into the periglacial environments of the lowland regions that existed in reasonably close proximity to continental ice sheets and mountain glacial systems. Over the last 2.6 million years, these glacial intervals have dominated Earth history. In fact, cold periods account for upwards of 90% of the Pleistocene epoch, while warm periods represent just 10%. In other words, from a long-term perspective, cold glacial conditions have been the norm for the past 2.6 million years, while warm interglacial conditions have been the exception.

Abstract

The alpine environment of the Andes encompasses a vast and continuous extension of regions above tree line, in which three main ecoregions are identified: Paramo (north), Puna and Altiplano (center) and Southern Andes (South). Along this region, 200 species of mammals are found; these belong to 10 orders and 27 families. Greater species richness is concentrated in two different areas, one at the ecotone between the Puna and the Yungas Montane forest, and the other within the southern portion of the Paramo. Both regions share species that are endemic or have their main distribution in the alpine or are broadly distributed species that only marginally reach high elevations.

Rodent species represent almost 70% of all Andean mammals, followed by bats and carnivores, which account for 8% and 5% respectively. Bats are only marginally present in the high Andes, whereas rodents encompass >40% of their range along the high Andes.

Andean mammals face several conservation threats, related mainly with habitat loss or transformation, climate change and invasive species introduction. Among Andean species, near 20% have some degree of conservation concern, while 15% are considered data deficient.

Introduction

The South American Andes extend over a north-south length of 8500 km, and are the world's longest mountain chain, with an elevation range from 700 to 7000 m asl. Within this region, three major geographical units can be identified: The Northern, the Central, and the Southern Andes (Sempere et al., 2008). Between the NA and CA, there is a transition zone termed "Amotape-Huancabamba". Its geography and topography provide an excellent scenario for the study and understanding of species distribution and biodiversity patterns.

The Andean uplift played an important role in the historical diversification of the Neotropical biota. It served as a source of new high elevation habitats (Young et al., 2007). It acted as a vicariant barrier, by promoting isolation of lowland organisms on either side of the mountains. It also represented a N-S corridor for several species (Patterson et al., 2012) and it generated a heterogeneous mosaic of habitats and micro-habitats (montane and inter montane valleys) where colonization and differentiation could occur. All these features contributed to the high diversity and endemism of this region (Novillo and Ojeda, 2012; Ceballos and Ehrlich, 2006; Maestri and Patterson, 2016).

The alpine environment of the Andes encompasses a vast and continuous extension of regions above tree line (Fig. 1A). To the north, this environment tends to be wetter and fragmented (Peru to Venezuela), where they are called "páramos." From southern Peru to central Argentina, the high-elevation communities are termed "puna" and the portion that extends across western Bolivia is

Fig. 1 (A) Alpine region along the Andes. (B) Alpine mammals richness. (C) Relationship between richness and latitude, using Alpine mammals separated into three groups: (1) N_richness—northern group (above the Amotape-Huancabamba depression); (2) C_richness—central group; (3) S_richness—southern group (below 20°S).

called “Altiplano”; both regions constitute a continuous arid province. The transitional communities above 3000 m in central Peru are known as “jalca”. Finally, the Southern Andes include the remaining Andean zones south of 29°S. Here, elevations tend to decrease from North to South (Pankhurst and Herve, 2007).

The Páramo comprises a number of neotropical high altitude grassland ecosystems, mainly in the upper parts of the Northern Andes. Its vegetation is mainly dominated by tussock grasses, dwarf shrubs, cushion plants and other forms of vegetation adapted to the cold, wind and intense ultra-violet radiation found at high altitudes. This region houses some rare and large species of mammals, such as the spectacled bear (*Tremarctos ornatus*), the mountain tapir (*Tapirus pinchaque*) and the white-tailed deer

(*Odocoileus virginianus*) (Kattan et al., 2004). Several large mammals of the Paramos are susceptible of local extinction or are characterized as endangered (Díaz et al., 1997). Additionally some studies have been done on Páramo rabbits (*Sylvilagus brasiliensis andinus*), and on the diversity and distribution of small mammals (Kattan et al., 2004). The Northern Andes are considered a hotspot for restricted-range species (those 25% of species with the smallest ranges), which places a high conservation status on this region (Ceballos and Ehrlich, 2006). In general, the Paramos are inhabited by almost 25 mammal species, most of which are rodents (Díaz et al., 1997).

Puna and Altiplano are the most arid portion of the alpine environment and they are also considered the oldest. These regions are considered a mixture of heterogeneous habitats, with marked zonal vegetation.

The biogeographical history of several species supports the antiquity of the Altiplano. Among the South American Camelids, the Vicugna shows a demographic expansion associated with the last major glacial event of the Pleistocene, an indication of former refugia (Marín et al., 2008). Also, the Guanacos show that the Puna and Altiplano acted as a geographic barrier between populations of the Northwest (Sechura and Atacama desert) and the Southeast (South from Bolivia) (Marín et al., 2008). Rodents also show the same pattern; Phyllotine rodents exhibit ancestral character states and basal positions on phylogenies, whereas lowland taxa tend to exhibit derived characters (Spotorno et al., 2001).

Several parallel ranges shape the Southern Andes: the Cordillera Principal, Cordillera Frontal and the Pre-cordillera. The highest elevational limits of the vegetation in this area are found at approximately 5000 m asl in the north and 3000 m in the south. The vertical relief is extremely abrupt and some of the highest peaks of the Andes occur in its northern portion. In the south, elevations generally decrease to <3000 m, but high volcanoes are frequent. Permanent snow, ice caps and glaciers are found in the summits of these elevations. The Southern Alpine Andes are rich in endemic plants (Luebert and Weigend, 2014), though this does not hold true for mammals. Most mammal species have large geographic ranges, extending north into the Puna and eastward into the Monte Desert and Patagonia (Novillo and Ojeda, 2012). Some endemic or near-endemic mammals are small ground living species, such as the rodents of the genus *Euneomys* and *Abrothrix andina* (Ojeda et al., 2015b).

Although it is commonly considered that cold-adapted ecosystems such as high mountain ranges are robust and change slowly compared to other ecosystems. However, they are especially sensitive to threats associated with climate change and land use changes (Nogués-Bravo et al., 2007, 2008).

The purpose of this contribution is to characterize the composition, distribution and conservation of the high Andean range mammal fauna.

Distribution Patterns

Along the Andes we registered 200 species of mammals, representing 10 orders and 27 families (Table 1). Species richness was higher at the ecotone between the Puna and the Yungas Montane forest, and within the southern portion of the Paramo (Fig. 1B). Below 20°S, there is a clear and sharp monotonic decreasing pattern, which also is shown in an East–West richness decline (Fig. 1B). When richness is evaluated along a north south transect, it is clear that richness decreases with increasing latitude from the Equator, both to the north and to the south from 20°S (Fig. 1C). The central and southern regions show an east to west decrease in species richness; meanwhile the northern region shows the opposite trend.

Rodents represent almost 70% of all Andean mammals, followed by bats and carnivores, which account for 8 and 5% respectively (Fig. 2A). Mean distributional range of all mammalian orders identified from the Andes accounted for less than half % of their overall ranges as a whole (Fig. 2B). A total of 19% of species can be considered regionally restricted or endemic (alpine range > 70%, 39 species). Indeed, most of the species have broad distributions that include the alpine environment to some extent, in some cases just marginally (see section Order Accounts).

Andean environments are potentially threatened by several anthropogenic factors, such as climate change and land use change, among others. Therefore, we expect that conservation concerns of several alpine species will increase in future. Among endangered species are the emblematic species, mountain tapir (*Tapirus pinchaque*), the only alpine representative of the order Perissodactyla, almost 20% carnivores, 5% of Chiroptera and 5% of Rodentia. If conservation categories such as ‘near threatened’ or ‘vulnerable’ are included, 40% of carnivores, 15% of Chiroptera and Didelphimorphia, 50% of Paucituberculata and 15% of rodents found in the alpine Andes are included as species of conservation concern (Fig. 2C). Additionally, several mammal orders have a high proportion of species whose conservation status is poorly known, including almost 50% of Cingulata, 15% of Didelphimorphia and 20% of rodents. These are categorized as “data deficient” (Fig. 2C).

Order Accounts

Ungulates (Order Cetartiodactyla)

The order is represented by two families (Camelidae and Cervidae), which encompass six genera and eight species (Fig. 3A). Among them only three registered >50% of their ranges along the Alpine Andes, and the rest registered <30% (Fig. 3B). Of these, 30% of camelids and 80% of the cervids are considered vulnerable of extinction (Fig. 3C).

Taxonomy, conservation status and % of their total range along the high Andes.

EN, endangered; LC, least concern; NT, near threaten; VU, vulnerable. IUCN red list categories. DD, data deficient.

Family Camelidae

South American Camelids encompass four species “Llama and Alpaca” (both domestic) and “Guanaco and Vicuña” (wild), all widely distributed in South America. Wild camelids form social groups that live in family groups, groups of bachelors and solitary individuals (Young and Franklin, 2004). Their mating system is polygynous for defense of resources, in which adult males defend territories of high forage quality and low predator density (Young and Franklin, 2004).

Camelids are intimately connected with Andean culture. At present, human use activities such as live capture and shearing could play an important role in the conservation of these species and their habitat (Carmanchahi et al., 2014).

The Guanaco (*Lama guanicoe*) ranges from northern Peru (8°30' S) to southern Tierra del Fuego (55°S), and from sea level up to 4857 m asl (Baldi et al., 2016). Historically, this species experienced significant population decline (Wheeler, 2012), and now its populations can be considered stable, mainly along its southern distribution (Schroeder et al., 2014). Guanaco habitat is characterized by seasonal climates in regions with low plant productivity. They are considered the largest (widely distributed) endemic herbivore of South-America, due to their anatomy, behavior and physiology (Puig et al., 2014; Ovejero et al., 2016).

Vicuñas (*Vicugna vicugna*) are restricted to fragmented areas of high elevation between 9°S and 29°S latitude in the Andes (Wheeler, 2012; and reference therein). DNA data suggest that their current distribution is the result of a westward expansion associated with glacial events during the Late Pleistocene 14–12,000 years ago (Wheeler, 2012).

Vicuña habitats include shallow wetlands “Vegas”, halophytic plant communities, steppes, prairies, and rolling shrub steppes (tolares) (Arzamendia and Vila, 2014). Vegas are intensively used by Vicuñas, given that they are obligate drinkers (Franklin, 2011). Water availability influences daily activity patterns, while in the night Vicuñas move to hillsides to avoid predation from pumas (Donadio and Buskirk, 2016). The Vicuña is considered a generalist herbivore that behaves as a facultative grazer that can also include shrubs in its diet (Mosca Torres and Puig, 2012; Mosca Torres et al., 2015).

Family Cervidae

Latin America has largest deer diversity in the world, with seven genera and 18 species thus far described (Wemmer, 1998). The alpine environment has 7 species in 4 genera (*Hippocamelus*, *Mazama*, *Odocoileus* and *Pudu*).

The genus *Hippocamelus* comprises two species, the “Taruka” (*Hippocamelus antisensis*), and the “Huemul” (*Hippocamelus bisulcus*). Taruka distribution extends through the highlands of the Andes from Peru to NE Chile (Barrio, 2013; Barrio et al., 2017), while the Huemul is endemic to Chile and Argentina (Vila et al., 2006). Both species’ distributions are fragmented with populations isolated from each other (Corti et al., 2011) and there is evidence of a decreasing population trend (Barrio et al., 2017; Flueck and Smith-Flueck, 2006). Tarukas are found between 2000 and 5000 m asl in rock outcrops within grassland vegetation and nearby water sources. Meanwhile, Huemul ranges from sea level up to 3000 m elevation, and is found mainly at the forest edge (*Nothofagus* spp.). Predation can be a major limiting factor and may even threaten species population viability (Elbroch and Wittmer, 2013). Several factors have been hypothesized to explain these species’ populations failure to recover (cattle, exotic trees, irrational forestry, exotic animals, illegal hunting, diseases, dogs, reduced numbers, loss of winter range) (Flueck and Smith-Flueck, 2006).

The genus *Mazama* has been the focus of a broad taxonomic debate. DNA studies suggest that this genus is polyphyletic (Gutiérrez et al., 2017). Three species of *Mazama* are found in the alpine Andes: *Mazama bricenii*, *Mazama chunyi* and *Mazama rufina*.

Fig. 2 (A) Percentage of High Andean mammals by Order. (B) Conservation status, percentage of species in each IUCN red list category. (C) Percentage of the species range encompass along the alpine region.

The ecology and general biology of the genus *Mazama* is unknown, although they seem to be solitary, active day and night, and with a browser/frugivore diet. In general, these species exhibit a decreasing population trend and are in need of further research.

Mazama bricenii "Mérida Brocket" is patchily distributed along the high Andes (1000–3500 m asl) in northern Colombia and western Venezuela, mainly along montane forests and in the Paramo (Lizcano and Alvarez, 2016). *Mazama chunyi* "Peruvian Dwarf Brocket" inhabits the highlands of southern Peru and northern Bolivia. Its current distribution and abundance need to be further assessed (Rumíz and Pardo, 2010). *Mazama rufina* "Dwarf Red Brocket" is found along the montane forest and the Paramos of Colombia, Ecuador and Peru, between 1500 and 3500 m asl.

Odocoileus virginianus "White tailed Deer" is a broadly distributed species that extends along the North and South American continents (Smith, 1991). In South America eight subspecies have been described, (Smith, 1991; Moscarella et al., 2003), among which 3 are present at the high Andes: (1) *O. v. goudotii* (Highlands Andes of Venezuela, Colombia, Ecuador and Northern Peru); (2) *O. v. ustus* (Andean region of Ecuador and Colombia); (3) and *O. v. peruvianus* (Peru and Bolivia, excluding amazon region) (Smith, 1991). South American populations are declining (Gallina and López-Arevalo, 2016), and conservation of the Andean subspecies is strongly suggested (Moscarella et al., 2003). White tailed deer diet is seasonal, and it can be considered as an opportunistic forager in the Paramos.

Pudu mephistopheles "Northern Pudu" is the only species of the genus present in the high Andes. Its range is fragmented, and it inhabits the montane forests and Paramos of Colombia, Ecuador and Peru. There is evidence of a high degree of isolation between populations (Loyola et al., 2010). Northern Pudu was intensively exploited from the 1950s to early 1980s. However, the current threats are mainly habitat conversion and predation by domestic dogs.

Fig. 3 (A) Percentage of High Andean carnivores by family. (B) Conservation status, percentage of species in each IUCN red list category. (C) Percentage of the species range encompass along the alpine region.

Carnivores (Order Carnivora)

Six carnivore families are found along the high Andes, comprising 10 genera and 11 species (Fig. 4A). Among them, Felidae (28% of the species) and Procyonidae (27%) are the best-represented. The Andean cat is the only carnivore that can be considered as endemic to the high Andes, with most of its range confined to high elevations (Fig. 4B). In general, most carnivores have only 15 to 20% of their ranges in the Andes (Fig. 4B). The families Felidae and Procyonidae have 30% of their species categorized as endangered, with another 30% considered vulnerable (Fig. 4C). The only bear (family Ursidae) found in the high Andes is the Andean Bear (*Tremarctos ornatus*); this species is categorized as vulnerable.

The family Canidae is represented by the “Culpeo” (*Lycalopex culpaeus*), which have a broad distribution throughout South America, from sea level to 4800 m asl (Ramírez-Chaves et al., 2013). Its population trend is stable, but culpeos are been persecuted throughout their range due to human conflicts (Lucherini and Merino, 2008). Also there is evidence for negative effects with coexistence with the puma (Travaini et al., 2007).

The family Felidae is represented in the Andes only by the “Pampas cat” (*Leopardus colocolo*), the “Andean cat” (*Leopardus jacobita*) and the “Puma or cougar” (*Puma concolor*). The pampas cat has a broad distribution in South America. Along the Andes, populations seem to be stable and may even reach high densities (0.74–0.78 individuals/km²), mainly along productive habitat patches (Lucherini et al., 2016). In the high Andes this cat’s diet includes mountain viscacha and small rodents (Napolitano et al., 2008; Fajardo et al., 2014).

The Andean cat has a patchy distribution in the Andes, restricted to rocky habitats above 3600 m (Argentina, Bolivia, Chile and Peru) (Cossios and Angers, 2007; Novaro et al., 2010; Reppucci et al., 2011). Genetic studies confirm two isolated populations that can be considered as “Evolutionary Significant Units” (ESUs); also these studies confirm that the species has very low genetic

Fig. 4 (A) Percentage of High Andean ungulates by family. (B) Conservation status, percentage of species in each IUCN red list category. (C) Percentage of the species range encompass along the alpine region.

diversity (Cossíos et al., 2012). The Andes cat may be considered as a habitat and diet specialist, with high proportions of rodents and mountain viscachas (*Lagidium spp.*) in its diet (Napolitano et al., 2008; Marino et al., 2010).

The puma is the largest carnivore of the region, with a broad distribution throughout the Americas. Due to conflicts with humans, pumas can be considered near threatened in specific places and have been categorized as least concern with a decreasing population trend by IUCN (Nielsen et al., 2015).

Ranges of several of these species overlap along the Andes (Lucherini et al., 2009), which may be leading to intraguild competition and a high degree of dietary overlap (Lucherini et al., 2008; Donadio and Buskirk, 2016). Evidence suggests a negative effect of competition among carnivores that may impact the most endangered species (Lucherini and Luengos Vidal, 2003; Napolitano et al., 2008). This competition among predators leads to ecological segregation by temporal partitioning (Lucherini et al., 2009).

The Procyonid family, “Coatis” extend along the northern Andes, from Northern Peru to Venezuela and display restricted or limited distributions (Helgen et al., 2009; González-Maya et al., 2011). The two species of *Nasuella* (*olivacea* and *meridensis*) were previously considered to be one, and the genus *Nasua* seems not to be monophyletic (Helgen et al., 2009). All three species of alpine procyonids exhibit decreasing population trends, mainly due to habitat loss (Helgen et al., 2009). There is little reliable information about their distribution, ecology, and biology (Balaguera-Reina et al., 2009). In general, the species are omnivorous, eating predominantly invertebrates and fruit (Rodríguez-Bolaños et al., 2000). Coatis are gregarious, with a complex social organization (Rodríguez-Bolaños et al., 2000).

The Molinas hog-nosed skunk, the only representative of Mephitidae family, has a broad distribution, from southern Peru to Chile and Argentina (Emmons et al., 2016). In general it is a common species with average densities of 3 individuals/km. It is a

nocturnal and solitary, with a generalist diet (Donadio et al., 2004). It is categorized as least concern by IUCN, but is currently showing a decreasing population trend (Emmons et al., 2016).

Mustelids are represented by the Lesser grison and Long-tailed weasel. Both are considered as least concern for conservation (Helgen and Schiaffini, 2016; Helgen and Reid, 2016). The former is a broadly distributed species (from Southern Peru to Argentina and Chile), which is frequently found near water and open habitats (Poo-Muñoz et al., 2014). It is relatively rare in most habitats. Its diet consists of small and medium-sized vertebrates, with a predominance of introduced lagomorphs and native rodents. Lesser grisons are active during the day, but also at dusk and may also be nocturnal. The long-tailed weasel tends to be solitary or to live in small groups. It has the greatest geographical range among mustelids of the Western Hemisphere and inhabits a wide array of habitats and elevations (Sheffield and Thomas, 1997). Mismatch analyses suggest a longer genetic stability of long-tailed weasel lineages in southern versus northern habitats (Harding and Dragoo, 2012).

The spectacled or Andean bear is the only extant representative of the Ursidae in South America (Kattan et al., 2004). Its geographic distribution extends along the tropical Andes from Venezuela to Bolivia-Argentina and it occupies a variety of ecosystems (García-Rangel, 2012). Its range is severely fragmented (mostly in the northern part); this entails conservation problems for the species, including isolated and small populations, habitat loss, altitudinal movement limitations, etc. (Troya et al., 2004). Andean bears are omnivorous, though the meat proportion of their diet is rather low (Troya et al., 2004). Populations are on the decline mainly due to habitat loss and fragmentation (Kattan et al., 2004; García-Rangel, 2012). Conservation actions are mainly focused on the preservation or development of habitat corridors for the species (Yerena and García-Rangel, 2010).

Bats (Order Chiroptera)

Chiroptera are the second most speciose order of mammals. Along the high Andes we registered 3 families, 11 genera and 19 species of bats (Fig. 5A), which in general encompass <20% of their ranges along the high Andes (Fig. 5B). Little information about habitat, activity patterns and general ecology is available for Andean bats. The Incan mastiff bat (*Mormopterus phrudus*) has most of its range (75%) in the high Andes, although this species is only known from the type locality in Cusco, Peru. There are few records of bat species above 3500 m, with the probable exception of *Histiotus montanus* (Handley Jr. and Gardner, 2008). Conservation status among Andean bats reveals that, among the family Vespertilionidae, 12% of the species are considered endangered, 10% of Phyllostomidae are near threatened and 30% of Molossidae are categorized as vulnerable (Fig. 5C). The Andean bat community is characterized by reduced species richness and little endemism (Mena et al., 2011).

Armadillos (Order Cingulata)

This order includes only the family Dasypodidae, commonly known as “armadillos or quirquinchos”. We found two genera that reach the high Andes region, each represented by a single species. The screaming hairy armadillo (*Chaetophractus vellerosus*) is distributed in the center and south of Bolivia (Tarifa and Romero-Muñoz, 2009), west of Paraguay and north of Argentina (Abba and Superina, 2010), generally in arid and semi-arid environments. The subspecies *C. v. vellerosus*, present in the Puna of Bolivia and Argentina, occurs at altitudes from sea level to 4600 m asl, and almost 20% of its distribution falls within the high Andes. It is considered, as least concern for conservation and its population trend is stable. However, this species is heavily hunted and its habitat has been intensively transformed (Superina et al., 2014). Its diet is omnivorous and it constructs burrows for refuge (Abba and Cassini, 2008). The hairy long-nosed armadillo (*Dasypus pilosus*) has been recorded only from the southwestern Peruvian Andes, and its distribution probably reaches the high Andean environment (Superina et al., 2014). Both morphology and invertebrate ecology support the hypothesis that *Dasypus pilosus* likely bases its diet on soft-bodied invertebrates. More studies are necessary to clarify its ecology and distribution (Superina and Loughry, 2015).

Opossums (Order Didelphimorphia)

This order includes the majority of the living American marsupials (Gardner, 2008). All of them are included in the family Didelphinae. Six species occur in the Andes, representing four genera. Most of them reach the margins of high elevations, mainly due to its arboreal habits and ecophysiological aspects (Fig. 6A). The Andean white eared opossum (*Didelphis pernigra*) is found along the Andes from northwestern Venezuela and Colombia to the north of Argentina (rare along the Puna and Paramo environment). *Gracilinanus aceramarcae* has a narrow distributional range, with a significant proportion of its range in the high Andes (Fig. 6B). It has been found in the Cordillera Vilcabamba at 3350 m, in a mixed habitat consisting of pajonales, sphagnum bogs, mixed-species forest, and Polylepis forest on a “blocky” limestone substrate (Voss et al., 2005). The Wood-sprite Opossum (*Gracilinanus dryas*) is known from the Andes of Venezuela and Colombia, mainly in montane wet forest at elevations from 2300 to 4000 m asl. This species is not endangered but its population trend is decreasing (Pérez-Hernandez et al., 2016). Osgood’s Short-tailed Opossum (*Monodelphis osgoodi*) is found in the eastern Andes in Perú and Bolivia from 1400 to 3500 m asl. Most records are from the montane forest; its presence on alpine regions is peripheral. This species is the least arboreal; its diet consists of insects, seeds and fruits (Nowak, 1999). Two species in the genus *Thylamys*, *T. venustus* and *T. pallidior* range into the high Andes. Both species have broad ranges in Argentina, Chile, Bolivia and Peru (Solari, 2003). The genus is in need of extensive taxonomic revision (Braun et al., 2005). Little information is available about *T. venustus*, so it is considered as data deficient in terms of conservation (Fig. 6B).

Fig. 5 (A) Percentage of High Andean bats by family. (B) Conservation status, percentage of species in each IUCN red list category. (C) Percentage of the species range encompass along the alpine region.

Fig. 6 Order Cingulata. (A) Conservation status, percentage of species in each IUCN red list category. (B) Percentage of the species range encompass along the alpine region.

Shrews (Order Eulipotyphla)

Andean shrews are represented by the family Soricidae and the genus *Cryptotis*, which encompass 8 species. Their range extends from Venezuela to Peru north of the Huancabamba depression (Woodman and Péfaur, 2008). *Cryptotis* is known only from elevations above 1200 m in a variety of habitat types (Lower and Montane Forest, Paramo, and in disturbed forest and pasture lands). Taxonomic treatments of the genus *Cryptotis* partition the species among four informal species groups. Most South American shrews are members of the *C. thomasi*-group, which is distinguished by a number of derived characters. Among this group, *C. equatorius* and *C. motivaga* comprise >50% of their ranges along high Andes (Fig. 7). In general, most of the species are distributed along the lower and montane forests and extend only marginally over the Paramo (Woodman and Díaz de Pascual, 2004). There is no clear conservation concern among shrews, although there is little information about their natural history. *C. peruvensis* is considered as data deficient, mainly as it is only known from two specimens (Vivar et al., 1997).

Shrew Opossums (Order Paucituberculata)

This order is represented by one family (Caenolestidae), which comprises 3 genera, known only from South America. We list only two genera (*Caenolestes* and *Lestoros*) and 4 species that reaches high Andes elevations, and whose geographic range extends discontinuously from western Venezuela to Bolivia (Timm and Patterson, 2008; Patterson, 2015). All species registered <40% of their ranges along the Andes (Fig. 8A), generally they inhabit montane forest, near streams or water courses, and may reach the high

Fig. 7 Order Eulipotyphla. Percentage of the species range encompass along the alpine region.

Fig. 8 Order Paucituberculata. (A) Conservation status, percentage of species in each IUCN red list category. (B) Percentage of the species range encompass along the alpine region.

elevations only marginally (Timm and Patterson, 2008; Patterson, 2015). Shrew opossums are mostly nocturnal, feeding on earthworms, flatworms, and several arthropods, both as larvae and adults (Patterson, 2015). *C. caniventer* and *C. convelatus* registered some conservation concerns, meanwhile *C. fuliginosus* and *Lestoros inca* are considered of least concern (Fig. 8B). Land transformation for agricultural purposes is among the mayor threats (Solari and Martínez-Cerón, 2015).

Páramo Rabbit (Order Lagomorpha)

The Páramo Rabbit, *Sylvilagus brasiliensis* has been classified as the subspecies *S. b. meridensis*, which inhabits all Venezuelan and Colombian páramos (Durant, 1983); and *S. B. andinus* is present at high elevations in Ecuador (Diersing and Wilson, 2017). Population density along Venezuela Páramos was estimated at 2.85 rabbits per ha. (Durant, 1983) and in Ecuador it ranged from 23 to 92 individuals/ha. Abundance is strongly associated with vegetation structure (García et al., 2016), since higher complexity and higher diversity of the vegetation leads to more possible refuges for rabbits to avoid predators and greater diversity of diet items. The size and abundance of rabbits make them an important Páramo prey species (García et al., 2016), therefore its presence and abundance are important for community structure (Durant, 1983). The Páramo rabbit has several adaptations that improve its survival at high elevations. It has a set of morpho-physiological specializations, including heavier fur with longer hairs, a longer gestation period, a reduction in the number of teats and in the number of offspring per litter, and strong territoriality (Díaz et al., 1997).

Mountain Tapir (Order Perissodactyla)

The mountain tapir is known from Andean region of Colombia, Ecuador and Northern Peru, above 1400–4700 m asl. Its population is heavily fragmented, therefore leading to a genetic bottleneck effect (Downer, 1997, 2001). Also this species displays several attributes (slow reproduction rate, large home range, solitary nature) that make it particularly vulnerable (Downer, 1997). Human activities, such as hunting, farming, mining and habitat conversion are among the major conservation threats (Lizcano et al., 2002). Also there is a great concern about the effects of climate change on mountain tapir populations (Ortega-Andrade et al., 2015).

Rodents (Order Rodentia)

Rodents comprise more than half of all Neotropical mammal species (Maestri and Patterson, 2016), and occupy most terrestrial environments (Lacher et al., 2016). They are separated into two groups: “caviomorphs or sigmodontines”, which have greater diversity (Patton et al., 2015; Upham and Patterson, 2015; Ojeda et al., 2015a, 2016). Previous studies showed that the Andes support high levels of species richness and turnover of rodents (Amori et al., 2013; Maestri and Patterson, 2016). Rodents encompass almost 70% of the mammals present at the Andes (Fig. 1A) and are the only small mammals that inhabit elevations above 4000 m. The family Cricetidae embraces almost 80% of all the Andean rodents (108 species); meanwhile the other families are represented by no >10% (Fig. 9A). Fifteen out of 44 genera are considered endemic to the Andean region, with >70% of their ranges constrained to this region (Fig. 9B). Around 50% of the species in the Andes are categorized as least concern, 15% are considered data deficient and 14% conveyed some conservation issue.

Among families, Chinchillidae constitute a high proportion of endangered species, while Caviidae and Cuniculidae contain species categorized as near threatened (Fig. 9C). Most families contain species for which conservation information is scarce; there are therefore categorized as data deficient. Among the family Cricetidae almost 5% of the species are considered endangered and almost 10% are considered vulnerable (Fig. 9C).

Caviomorph rodents radiated in the Neotropics and now occupy a wide spectrum of landscapes, elevations, and habitats here (Ojeda et al., 2016; Upham and Patterson, 2015). The Ctenomyidae and Chinchillidae are mostly distributed in temperate regions. Tuco-tucos (Ctenomyidae) have a wide distribution from southern Peru to Tierra del Fuego, and from Andean Puna to the Atlantic coast (Upham and Patterson, 2015), several species show restricted distributional ranges and some are known only from the type locality (Ojeda et al., 2016). On the other hand Chinchillas extend from the central Andes to southern Patagonia. Specifically, the genera *Chinchilla* and *Lagidim* are restricted to Altiplano and Puna environments (Valladares et al., 2014; Ojeda et al., 2015a, 2016). The main threats for Chinchilla populations are mining exploitation and commercial hunting for the fur trade (Valladares et al., 2014).

The distribution patterns of the families Octodontidae and Abrocomidae extend along the arid Andes (Upham and Patterson, 2015). Among Octodontids, the mountain degu (*Octodontomys gliroides*) lives in dry Andean zones of northern Chile, Bolivia and northwest Argentina, mostly in rocky areas with herbaceous vegetation (Verzi et al., 2015). On the other hand, the chinchilla rats (Abrocomidae) show restricted and non- overlapping ranges along the southern Andes (Woods and Kilpatrick, 2005). The family Caviidae shows the broadest distribution among caviomorphs and includes most major biomes. The highest species density occurs in the dry south-central Andes, in the Cerrado and Caatinga ecoregions (Ojeda et al., 2015a).

The Echimyidae, Erethizontidae and Sciuridae are mainly found in tropical forests, with high diversity along the Yungas and in Amazonia. Most species occupy arboreal habits and may reach the Alpine region marginally, mostly in the Páramos of Colombia and Venezuela (Ojeda et al., 2016; Upham and Patterson, 2015).

Fig. 9 (A) Percentage of High Andean rodents by family. (B) Conservation status, percentage of species in each IUCN red list category. (C) Percentage of the species range encompass along the alpine region.

The geographic distribution of the family Cuniculidae extends from central Mexico to northern Argentina (Ojeda et al., 2015a). Species density is highest in the tropical Andes region (Ojeda et al., 2015a; Upham and Patterson, 2015). Only the Mountain Paca (*C. taczanowskii*) is found in the high Andes of Peru, Ecuador, Colombia, and Venezuela (Woods and Kilpatrick, 2005), between elevations of 2000 and 3500 m asl. This species is considered as near- threatened due to habitat destruction, invasive species and hunting pressure (Zapata-Ríos and Branch, 2016).

Among cricetid rodents, some genera are mainly Andean in distribution (*Chinchillula*, *Auliscomys*, *Punomys*, among others) and others with broad distributions in other ecoregions that extend into the Andes (*Akodon*, *Oligoryzomys*, *Oxymycterus*, etc.) (Patton et al., 2015). Half of the genera present in the high Andes area have >50% of their ranges in this region (Fig. 10A). Almost 70% of these species are considered as least concern, while 10% are poorly known and categorized as data deficient, plus 20% that have some level of conservation issues (Fig. 10B).

Alpine rats and mice's ranges confirm that the Huancabamba depression separates two different groups: a northern and a southern one (Fig. 10C). The Central Andes was recognized as an important area for sigmodontines differentiation (Novillo and Ojeda, 2012; Maestri and Patterson, 2016; and reference therein). Therefore the Puna and the Altiplano are considered to harbor high species endemism (Ojeda et al., 2000).

Concluding Remarks

One of South-America's most vexing and polarizing challenges is how best to manage public lands established for multiple uses such as natural resource extraction, wildlife, and recreation. The intersection between energy development and biological conservation affords opportunities both to gather knowledge and to implement findings about how to mitigate impacts to wildlife, without neglecting local and regional development. Among all species registered in the Andes, 32% of rodents, 25% of ungulates and 5% of bats and carnivores can be considered endemics, with >70% of their ranges found in the Alpine region. Most of these species show adaptations to harsh climate (low temperatures and oxygen pressure) (Ostojic et al., 2002); and are habitat specialists confined to a specific habitat type (Andean cats, mountain vizcachas, vicuñas, among others).

As the footprint of human development continues to expand globally into regions that have historically supported abundant wildlife resources, there will be even more pressing needs for long-term data collection, in conjunction with baseline data, to examine changes in life history parameters and behavioral processes. Mountains are fragile environments (Díaz et al., 2003), which are strongly affected by climate change and several anthropogenic pressures (Young, 2009). Mountain regions are highly sensitive to climate change, and show above average warming, in comparison to global means during the 20th century (IPCC, 2014; Nogués-Bravo et al., 2007). Therefore, under this scenario elevational shifting of climatic belts is expected to occur, with concomitant effects on biodiversity. Species are expected to shift their distributions upslope in response to warming; however, there may no longer be appropriate habitat on mountain summits, leading to a high likelihood of Alpine species extinction (Oppenheimer et al., 2014). For example, regions of highest mammals richness (southern Paramo and the Puna/Altiplano, Fig. 1) will experience a temperatures rise up to 5°C (IPCC, 2014; Baez et al., 2016). This future scenario may lead to an upward shift of tree limit, reducing the alpine environment area, and constraining the suitable environment of several species. There is evidence of mountain species extinctions due to severe range contraction among endemic species (Parmesan, 2006) and that species from tropical latitudes are unlikely to evolve physiological tolerances to heat increase, being more affected by climate change (Araújo et al., 2013.). Among rodents, high Andean species show that animals from mid- and high elevations reduced their activity under high temperatures; this behavior decreases animal foraging and reproducing time, leading to fitness reduction (Sassi et al., 2015).

Conflicts between humans and wildlife occur when the interests and objectives of human activities, such as extensive and intensive livestock farming, agriculture and extractive activities do not take into account the native flora or fauna of the landscape, much less its functional diversity in a perspective of conservation of ecosystem services. Anthropogenic activities such as land change use for farming (small and large scale agriculture), oil and gas prospecting, invasive species introduction (feral dogs), and city expansion, are among the major threats to biodiversity (Zapata-Ríos and Branch, 2016; Salvador et al., 2014). Such unplanned activities represent a key challenge for society because their negative impacts can affect food security (wildlife damaging crops), the sustainability of ecosystems (over-exploitation of available resources) and biodiversity (human dimension as an agent of stress, loss of habitat and functional diversity, displacement of native species by exotic species). Thus, the sum of the effects of human activities can threaten the integrity of ecosystems on which both biodiversity (fauna and flora) and agriculture and livestock depend, i.e. whether the species that provide key ecosystem services (nutrient cycling, pollination, etc.)

In summary Alpine environments are fragile, vulnerable and lack the required resilience to withstand future changes (Gonzalez et al., 2010). They are inhabited by cold adapted species in most cases with restrictions to migrate, or adapt to new scenarios. Therefore these regions should be a top priority when studying the effects of climate change (Dirnböck et al., 2011; Laurance et al., 2011) and among conservation actions.

Abstract

The African alpine (Afroalpine) zone is poorly defined and generally considered part of the wider Afromontane region. We consider the Afroalpine zone as areas exceeding 1800 m elevation. These zones occur as isolated pockets, stretching across large parts of tropical and sub-tropical Africa. Afroalpine habitats are isolated on mountain tops, supporting fragmented and unique vegetation types. Afroalpine mammals are represented by 10 orders, currently comprising 109 species, 60% of which are endemic. Of concern is that 38% are endangered, a number that is likely to increase in future. Rodents comprise 53% of the Afroalpine mammal species and are generally better studied than other groups. Some are specialists occupying a narrow altitudinal range while others are generalists, occupying a wider range of elevations. Afroalpine rodents show a range of adaptations to their habitats to minimize exposure to lethal temperatures. We present two case studies, one of the non-specialist ice rat, whose success depends on behavioral and morphological adaptations, and the other of the charismatic Ethiopian wolf, whose specialized diet and habitat use makes it vulnerable to extinction. Afromontane mammals face a range of threats, most notably habitat destruction through human expansion and activity and ultimately global climate change.

Definition and Distribution of African Alpine (Afroalpine) Region

The word alpine conjures up visions of sparkling snowy slopes in temperate regions of Europe, from where the term originates. However, 'alpine' can also refer to regions occurring in other parts of the world, in particular to vegetation above the altitudinal tree line. Africa's alpine zones, known as the Afroalpine, are extensive and span temperate, tropical and equatorial regions of sub-Saharan Africa. Yet, while the term Afroalpine appears sporadically in the literature, historically there has been little consensus about what constitutes Africa's alpine region, as discussed below.

The term Afroalpine was coined by [Hauman \(1955\)](#) to refer to species-poor floristic areas, characterized by giant rosette life forms occurring in the East African tropical high mountains of > 3000 m elevation. Generally, Afroalpine habitats are characterized by short and sparse vegetation, as seen in the Ethiopian highlands ([Sillero-Zubiri and Gottelli, 1994](#)) and the southern African Drakensberg ([Schwaibold and Pillay, 2010](#)). The uppermost regions of these mountains act as refugia for unique flora with patchy distribution, characterized by the occurrence of plants such as giant *Senecio*, giant *Lobelia*, shrubby *Alchemilla*, and containing representatives of many genera not seen in the lowlands of tropical Africa. These plants are present on the high mountains of Ethiopia, with a few species extending to the Yemen, Cameroon, south tropical Africa, and South Africa ([Hedberg, 1961](#)). In southern Africa,

Coetzee (1967) coined the term Austro-afroalpine to distinguish the ecological belt in Lesotho and the Drakensberg Mountains in Southern Africa from the one recognized by Hauman (1955) in East Africa. The term subalpine has also been used in the Austro-afroalpine context in Southern Africa, but the term has not been applied consistently. For example, Thode (1894, cited in Killick, 1978) described the uppermost region between 2130 and 3050 m elevation of the South African Drakensberg, as subalpine. In contrast, Killick (1963) and Edwards (1967) used this term for the vegetation between 1830 and 1980 m and 2865–2895 m elevations respectively. Jacot Guillarmod (1971) described the subalpine belt in Lesotho as that lying between 2290 and 2900 m elevation. Coetzee (1967) rejected the idea of a subalpine region due to the lack of tall coniferous trees above the montane forests, which is typical of the European Alps, and proposed that the upper level of the montane forest represents the tree line and the vegetation above this level constitutes the Austro-afroalpine belt.

The contentious issues of the definition of the Afroalpine zone appear to center around geographic context (i.e. country and elevation) and floral composition. For the purposes of our review, we adopted a broader, more pragmatic view of Afroalpine regions as those occurring above 1800 m elevation, thereby casting a wider net to capture the mammal biodiversity. This approach combines the Afroalpine with upper elevations of most Afromontane areas (see <https://en.wikipedia.org/wiki/Afromontane>), and thus we consider largely Afromontane mammals in our appraisal, unless the literature specifically mentions Afroalpine mammals. In addition, we sometimes considered mammals at lower elevations if there was a likelihood that their distribution might breach the 1800 m cut-off.

The Afroalpine area as defined here comprises six disjunct zones (Fig. 1), occurring in western, eastern and southern Africa. In West Africa, the Afroalpine zone occurs along the Cameroon Highlands. In East Africa, the distribution of these zones follows a chain of isolated mountain peaks and plateaus, stretching from Ethiopia in the north to Zimbabwe and the Drakensberg mountain range in South Africa in the south. This distribution follows the Western, Eastern and Southern Rift and includes the following countries: Uganda, Rwanda, Burundi, Democratic Republic of the Congo, Kenya, Tanzania, and Zimbabwe. The mountains and plateaus are

Fig. 1 Afroalpine distribution. 1. Cameroon highlands, 2. Ethiopian highlands, 3. Western Rift, 4. Eastern Rift, 5. Southern Rift and Eastern Highlands, 6. Drakensberg/Maluti. separated by lower savannas and woodlands (White, 1983). Aptly stated by Kingdon (1989), the mountains represent “Africa’s Galapagos islands” with each mountain and plateau existing as a habitat island, supporting a characteristic fauna and flora.

Several biological phenomena are generally associated with changes in elevation and this is also true of the Afromontane areas. For example, the climate becomes more temperate and alpine, with seasonal or regular frost, low rainfall and snow at the highest elevations (Happold and Happold, 1989). Snow is even permanent at the higher reaches of equatorial Mount Kilimanjaro (Willis, 2000). Distinct altitudinal zones are apparent, with different plant and animal assemblages. In addition to elevation, several other factors contribute to the formation of different vegetation zones, such as latitude, aspect and the location of the mountain. For example, while Afroalpine grassland can occur as low as 1500 m above sea level in the Drakensberg region, it occurs only above 3800–4000 m elevation in the equatorial mountains of East Africa (Hamilton, 1982). This is because the effects of latitude and elevation are inter-related, and thus climatic conditions at higher elevations are similar to the conditions at lower elevations further away from the equator.

The unique geographical contexts of latitude and elevation are the primary drivers of the evolution of a plethora of endemic animal and plant species, particularly in the Afromontane ecosystem. While there are ample studies documenting the flora in relation to zonation in African mountains (Hedberg, 1957; White, 1981, 1983; Killick, 1978), studies on vertebrates are limited in the literature and are often only anecdotal reports. Nonetheless, small terrestrial mammals at high elevations on African mountains have been comparatively well studied, for example in Mount Ruwenzori, Mount Cameroon, Mount Kahuzi, Mount Elgon (Clausnitzer, 2001), Mount Kenya (Moreau, 1945), Mount Kilimanjaro (Grimshaw et al., 1995), Drakensberg (Rowe-Rowe and Meester, 1982; Perrin and Carranza, 2000), and the Maluti Mountains (Hinze and Pillay, 2006).

African Alpine Mammals

Afroalpine habitats are poorly studied in many of the representative countries because of their inaccessibility, the small number of field biologists and a lack of consistent field surveys. There have been some recent attempts to conduct small mammal studies in West Africa by personnel at the Natural History Museum in Paris (Christiane Denys pers. com) and there have been sporadic studies by field biologists in Kenya. Several long-term studies have been conducted in the Bale Mountains in Ethiopia. In Southern Africa, studies in the South African and Lesotho Drakensberg are routinely conducted by biologists from both countries (details below).

Based on historical and current studies, 10 orders of mammals occur in Afromontane areas, including Rodentia (58), Insectivora (27), Carnivora (7), Cetartiodactyla (6), Primates (5), Hyracoidea (2), Chiroptera (1), Lagomorpha (1), Macroscelidea (1) and Tubulidentata (1). At the time of this writing, we identified 109 mammal species, representing 20 families (Table 1). We expect these numbers to change as better sampling is undertaken and better systematic assessments appear in the literature in future (Christiane Denys pers. com).

Of the 109 species, 60% (65) are endemic, mostly to Ethiopia (29) and the Cameroon (16). About 38% of the mammals are of conservation concern, including 3 critically endangered, 16 endangered and 22 vulnerable/threatened. Most (60; 55%) are of least concern and we could not find the status of 7% (8) of mammal species (IUCN, 2017). Specifically, of the endemic species, a staggering 57% (37) are of conservation concern (mostly those from Ethiopia and Cameroon; IUCN, 2017). Three large mammals are endangered, including the Walia ibex *Capra ibex waliae*, Mountain Nyala *Tragelaphus buxtoni* and the Ethiopian wolf *Canis simensis*, all from Ethiopia. The remaining species belong to the orders Rodentia and Insectivora.

Rodents

As evident from Tables 1, 53% of the species are rodents, the most speciose mammal order globally. Most (35, 60%) of these are endemic. This high rodent endemism reflects the unique geological and biogeographic history, topography, variation in climatic conditions and a wide range of vegetation types in disjunct mountain ranges, promoting high biodiversity and endemism in countries with Afroalpine habitats (Yalden and Largen, 1992; Bekele, 1996; Clausnitzer, 2003). Generally, the distribution and abundance of rodent species are influenced by various environmental factors, such as vegetation, climatic conditions, disease, predation, life history strategies and human encroachment (Marino, 2003; Fitzherbert et al., 2007). For example, in the Bale Mountains, a higher density of rodents occurs in *Alchemilla* meadows and rocky grasslands and lower densities occur in the *Helichrysum* heaths and *Artemisia* grasslands (Marino, 2003), showing the influence of vegetation on life history biology.

Some Afroalpine rodents inhabit a narrow elevational range, including many of the Ethiopian endemic species listed in Table 1, whereas others are elevation generalists (Yihune, and Bekele, 2012). As expected, non-endemic rodent species are not restricted geographically and inhabit a wide range of montane habitats above 3000 m elevation and also occur at lower elevations. Examples include the four-striped mouse *Rhabdomys* spp., North-east African mole rat *Tachyoryctes splendens*, Northern groove-toothed rat *Otomys typus* and Abyssinian grass rat *Arvicanthis abyssinicus*, and the yellow-spotted brush-furred rat *Lophuromys flavopunctatus*. In particular, the ability of the yellow-spotted brush-furred rat to thrive in unfavorable habitats such as heathlands reflects its generalist nature (Yalden and Largen, 1992; Happold and Happold, 1992). Endemism is not related to ecological specialization, however. For example, some Ethiopian endemic rodent species are habitat specialists (e.g. grassland: Blick’s grass rat *Arvicanthis blicki*; Lovat’s climbing mouse *Dendromus lovati*; *Tachyoryctes macrocephalus*; shrubland: Nikolaus’s mouse *Megadendromus nikolausi*). Others are habitat generalists, such the Ethiopian narrow-headed rat *Stenocephalemys albocaudata* and Gray-tailed narrow-headed rat *Stenocephalemys griseicauda* that occupy grassland and shrubland.

Table 1 A current list of mammal species by order occupying Afro-montane habitats, including their endemism, ecological specialization and conservation status.

	Order	Species (common name)	Family	Endemism	Generalist/ Specialist	Conservation status	Reference(s)
1	Carnivora	<i>Canis simensis</i> (Ethiopian wolf)	Canidae	Endemic to Ethiopia	Specialist	Endangered	Sillero-Zubiri et al. (1997)
2	Carnivora	<i>Crocuta crocuta</i> (Spotted hyaena)	Hyaenidae	Wide distribution	Generalist	Least concern	Grimshaw et al. (1995)
3	Carnivora	<i>Genetta maculata</i> (Large spotted genet)	Viverridae	Wide distribution	Generalist	Least concern	Grimshaw et al. (1995)
4	Carnivora	<i>Herpestes ichneumon</i> (Egyptian mongoose)	Herpestidae	Wide distribution	Generalist	Least concern	Grimshaw et al. (1995)
5	Carnivora	<i>Leptailurus serval</i> (Serval)	Felidae	Wide distribution	Generalist	Least concern	Grimshaw et al. (1995)
6	Carnivora	<i>Lutra maculicollis</i> (Spotted-necked otter)	Mustelidae	Wide distribution	Specialist	Threatened	Perrin and Carranza (2000) and IUCN red list
7	Carnivora	<i>Panthera pardus</i> (Leopard)	Felidae	Wide distribution	Generalist	Vulnerable	Grimshaw et al. (1995)
8	Cetartiodactyla	<i>Capra ibex walie</i> (<i>Walia ibex</i>)	Bovidae	Endemic to Ethiopia	Generalist	Endangered	Brown (1969)
9	Cetartiodactyla	<i>Nesotragus moschatus</i> (Suni)	Bovidae	Wide distribution	Generalist	Least concern	Grimshaw et al. (1995)
10	Cetartiodactyla	<i>Sylvicapra grimmia</i> (Common duiker)	Bovidae	Wide distribution	Generalist	Least concern	Grimshaw et al. (1995)
11	Cetartiodactyla	<i>Syncerus caffer</i> (African buffalo)	Bovidae	Wide distribution	Generalist	Least concern	Grimshaw et al. (1995)
12	Cetartiodactyla	<i>Tragelaphus oryx</i> (Eland)	Bovidae	Wide distribution	Generalist	Least concern	Grimshaw et al. (1995)
13	Cetartiodactyla	<i>Tragelaphus buxtoni</i> (Mountain nyala)	Bovidae	Endemic to Ethiopia	Generalist	Endangered	Evangelista et al. (2007)
14	Chiroptera	<i>Myotis scotti</i> (Scott's mouse-eared bat)	Vespertilionidae	Endemic to Ethiopia	Specialist	Vulnerable	IUCN red list
15	Hyracoidea	<i>Dendrohyrax validus</i> (East tree hyrax)	Procaviidae	Endemic to Kenya/Tanzania	Specialist	Threatened	Grimshaw et al. (1995)
16	Hyracoidea	<i>Procavia capensis</i> (Rock hyrax)	Procaviidae	Wide distribution	Generalist	Least concern	IUCN red list
17	Insectivora	<i>Crocidura allea</i> (East African highland shrew)	Soricidae	Endemic to Kenya/Tanzania	Specialist	Vulnerable	Grimshaw et al. (1995)
18	Insectivora	<i>Crocidura baileyi</i> (Bailey's shrew)	Soricidae	Endemic to Ethiopia	Specialist?	Least concern	Yalden and Largen (1992) and IUCN red list
19	Insectivora	<i>Crocidura bottegoides</i> (Bale shrew)	Soricidae	Endemic to Ethiopia	Specialist	Endangered	Hutterer and Yalden (1990)
20	Insectivora	<i>Crocidura eisentrauti</i> (Eisentraut's shrew)	Soricidae	Endemic to Cameroon	Specialist	Vulnerable	Cronin et al. (2014)
21	Insectivora	<i>Crocidura glassi</i> (Glass's shrew)	Soricidae	Endemic to Ethiopia	Specialist	Vulnerable	IUCN red list
22	Insectivora	<i>Crocidura harena</i> (Harena shrew)	Soricidae	Endemic to Ethiopia	Specialist	Critically Endangered	Hutterer and Yalden (1990)
23	Insectivora	<i>Crocidura lucina</i> (Lucina's shrew)	Soricidae	Endemic to Ethiopia	Specialist	Vulnerable	IUCN red list
24	Insectivora	<i>Crocidura monax</i> (Kilimanjaro shrew)	Soricidae	Endemic to Tanzania	Specialist	—	Grimshaw et al. (1995)
25	Insectivora	<i>Crocidura montis</i> (Montane white-toothed shrew)	Soricidae	Wide distribution	Generalist	Least concern	Clausnitzer et al. (2003)
26	Insectivora	<i>Crocidura olivieri</i> (African giant musk shrew/Olivier's shrew)	Soricidae	Wide distribution	Generalist	Least concern	Grimshaw et al. (1995)
27	Insectivora	<i>Crocidura phaeura</i> (Guramba shrew)	Soricidae	Endemic to Ethiopia	Specialist	Endangered	IUCN red list
28	Insectivora	<i>Crocidura picea</i> (Cameroonian shrew)	Soricidae	Endemic to Cameroon	Specialist	Endangered	Cronin et al. (2014)
29	Insectivora	<i>Crocidura thalia</i> (Thalia's shrew)	Soricidae	Endemic to Ethiopia	Generalist	Least concern	IUCN red list
30	Insectivora	<i>Crocidura zaphiri</i> (Zaphir's shrew)	Soricidae	Endemic to Ethiopia	—	—	IUCN red list
31	Insectivora	<i>Myosorex babaulti</i> (Babault's mouse shrew)	Soricidae	Wide distribution	Specialist	Least concern	Kingdon (1981) and IUCN red list

32	Insectivora	<i>Myosorex blarina</i> (Montane mouse shrew)	Soricidae	Wide distribution (Congo, Uganda)	Specialist	Endangered	Kingdon (1981) and IUCN red list
33	Insectivora	<i>Myosorex eisentrauti</i> (Eisentraut's mouse shrew)	Soricidae	Endemic to Cameroon	Specialist	Critically Endangered	Cronin et al. (2014)
34	Insectivora	<i>Myosorex okuensis</i> (Oku mouse shrew)	Soricidae	Endemic to Cameroon	Specialist	Vulnerable?	Cronin et al. (2014) and IUCN red list
35	Insectivora	<i>Myosorex varius</i> (Forest shrew)	Soricidae	Wide distribution (Lesotho, South Africa, Swaziland)	Generalist	Least concern	Rowe-Rowe and Meester (1982)
36	Insectivora	<i>Myosorex zinki</i> (Kilimanjaro mouse shrew)	Soricidae	Endemic to Tanzania (Mt Kilimanjaro)	Generalist	Least concern	Stanley et al. (2011)
37	Insectivora	<i>Paracrocidura maxima</i> (Greater large-headed shrew/Greater shrew)	Soricidae	Endemic to Bwindi Impenetrable National Park, Uganda	Specialist	Least concern	Kasangaki et al. (2003)
38	Insectivora	<i>Scutisorex somereni</i> (Armored shrew)	Soricidae	Wide distribution	Specialist	Least concern	Churchfield et al. (2007)
39	Insectivora	<i>Sylvisorex camerunensis</i> (Cameroonian forest shrew)	Soricidae	Endemic to Cameroon	Specialist	Vulnerable	Cronin et al. (2014)
40	Insectivora	<i>Sylvisorex granti</i> (Grant's forest shrew)	Soricidae	Wide distribution	Generalist	Least concern	Grimshaw et al. (1995)
41	Insectivora	<i>Sylvisorex lunaris</i> (Crescent shrew/Moon forest shrew)	Soricidae	Endemic to Bwindi Impenetrable National Park, Uganda	Specialist	Threatened	Kasangaki et al. (2003) and IUCN red list
42	Insectivora	<i>Sylvisorex morio</i> (Mt. Cameroon forest shrew/Arrogant shrew)	Soricidae	Endemic to Cameroon	Specialist	Endangered	Cronin et al. (2014) and IUCN red list
43	Insectivora	<i>Sylvisorex vulcanorum</i> (Volcano shrew)	Soricidae	Endemic to Bwindi Impenetrable National Park, Uganda	Generalist	Least concern	Kasangaki et al. (2003)
44	Lagomorpha	<i>Lepus starcki</i> (Ethiopian highland hare)	Leporidae	Endemic to Ethiopia	Generalist	Least concern	IUCN red list
45	Macroscelidae	<i>Rhynchocyon udzungwensis</i> (Gray-faced sengi)	Macroscelidae	Endemic to Tanzania	Specialist	Vulnerable	Stanley et al. (2011) and Rovero et al. (2008)

Adaptations to Afroalpine Life

Hedberg (1957) characterized Afroalpine climatic conditions as “winter every night and summer every day” (p. 10). Small mammals elsewhere cope with such variable diurnal conditions through diverse adaptations. For example, they could increase locomotion (Kauffmann et al., 2003), hibernate, enter torpor (McNab, 1974, 1983), have longer and denser fur, darker coloration and exhibit diurnal foraging behavior (Young and Evans, 1993) or display huddling behaviors (Gilbert et al., 2010). Since more is known about small Afroalpine mammals, particularly rodents, we focus on rodents for the most part hereafter.

The extremely low night temperatures experienced at high elevations impose constraints on the activity patterns of rodents generally, largely because of their small body size and greater heat loss (Cheviron et al., 2012). There is evidence that several Afroalpine rodents show behavioral, morphological and physiological adaptations to cold. To avoid lethal ambient temperatures in the Bale mountains, some rodents are diurnal, such as the yellow-spotted brush-furred rat, Abyssinian grass rat, Blick's grass rat, black-clawed brush-furred rat *L. melanonyx* and the Northern groove-toothed rat (Yalden, 1988; Sillero-Zubiri et al., 1995a). Utilizing protected nest sites, such as a burrow, can also provide thermoregulation benefits (Marino, 2003) for Afroalpine rodents. For example, the nocturnal yellow-spotted brush-furred rat and gray-tailed narrow-headed rat are found in areas dominated by shrubs and rocky boulders, which may provide protection against the lethal, subfreezing temperatures of their open valley habitats (Sillero-Zubiri et al., 1995b). The dense fur of the gray-tailed narrow-headed rat also confers a thermoregulatory advantage, enabling it to exploit many habitat types (Ashenafi et al., 2012). In addition, the comparatively large body and perhaps a slow metabolic rate of the Ethiopian narrow-headed rat enable it to utilize shallow burrows in areas where shallow soil or the danger of flooding exists (Ashenafi et al., 2012).

Soil depth is believed to limit the distribution of the giant mole rat in the Bale mountains, due to the thermoregulatory costs of burrowing. Despite large diurnal fluctuations in air temperature, the temperature remains more or less constant at a soil depth of 50 cm (Sillero-Zubiri et al., 1995a) and even in shallower burrows (Hinze et al., 2006). As such, small mammals can avoid harsh cold temperatures by nesting belowground (Sillero-Zubiri and Gottelli, 1995; Sillero-Zubiri et al., 1995a; Ashenafi et al., 2012), adopting a fossorial or semi-fossorial existence.

There are some other adaptations in Afroalpine rodents not related to thermoregulation. Stenocephaly, the narrowing of the interorbital area, reduces the distance between the eyes which become close-set and dorsally placed. In giant mole rats, stenocephaly enhances stereoscopic vision, enabling better detection of predators in its open short grass habitats (Yalden, 1975; Yalden and Lagen, 1992; Sumbera et al., 2018).

Case Study 1: African Ice Rat *Otomys sloggetti robertsi*

Ice rats are diurnal herbivores, endemic to the subalpine and alpine regions (>2000 m) of the Drakensberg and the Maluti mountains of southern Africa. They do not hibernate or enter torpor (Hinze et al., 2006). Laboratory experiments by Richter et al. (1997) highlighted three points demonstrating that ice rats are also poorly adapted physiologically to low temperatures. Firstly, their oxygen consumption (VO₂) decreases linearly with increasing temperature between 0.7 °C and 26.0 °C, with the zone of thermoneutrality occurring between 26 °C and 28 °C. Secondly, they can tolerate temperatures higher than those which are experienced in their habitat (e.g. 34 °C in contrast to natural range of 15–23 °C). Thirdly, their metabolic rate was higher than predicted, but thermal conductance was greater than expected, creating a % metabolic rate: % thermal conductance ratio of 0.87, which corresponds to values obtained for many arid/warm-adapted mammals. Richter et al. (1997) concluded that the metabolic rate and greater thermal conductance of ice rats did not appear to be sufficient to counteract the relatively high rate of heat loss at low temperatures. Moreover, their body temperature remained fairly constant even at low temperatures, which is energetically costly, as metabolic rates were almost twice as high at low temperatures than within its thermoneutral zone. Yet, they are locally abundant in Afroalpine habitats in Southern Africa, which warranted further intensive scientific research.

To cope with its challenging Afroalpine environment, ice rats have evolved morphological and behavioral adaptations. They possess a short tail and small ear pinnae to reduce heat loss (Richter et al., 1997). Their fur density of 1000 hairs per cm² potentially reduces heat loss through improved insulation. The fur density of other members of its family (Otomyinae) that live in arid regions is only one-fifth that of ice rats (Rymer et al., 2007). Compared to low elevation otomyines, ice rats have a larger small intestine, caecum, stomach volume and parts of the colon, which are possible adaptations for increased energy uptake and/or poor diet quality in alpine environments (Schwaibold and Pillay, 2003). Interesting seasonal sexual differences have also been observed, with females increasing dimensions of the stomach, small intestine length, caecum, and large intestine in summer. Such changes were absent in males. Morphological plasticity in females is apparently related to increased energy requirements during pregnancy and lactation, in response to poor quality vegetation and a shorter growing season in their alpine habitats (Schwaibold and Pillay, 2003).

Ice rats live in small colonies of 4 to 17 individuals, which collectively construct intricate belowground burrows. These burrows buffer extremes in aboveground temperatures throughout the year and provide opportunities for communal huddling belowground (Hinze et al., 2006). Moreover, their extensive interlinking tunnels provide underground access routes to aboveground feeding sites, thereby reducing exposure to adverse conditions (Hinze et al., 2006). Hinze and Pillay (2006) showed that ice rats have a bimodal diurnal activity profile aboveground in summer, retreating into their burrows during the middle of the day when ambient temperatures and solar radiation levels were at their highest. In contrast, in winter, a unimodal activity profile

was evident. They alter their behavioral profile seasonally by spending more time foraging and basking in winter and remaining belowground in their burrows for longer periods in summer (Schwaibold and Pillay, 2006). Basking, by drawing in the limbs closer to the body and pilo-erecting the fur (Fig. 2), reduces thermoregulatory costs for ice rats (Hinze and Pillay, 2006).

Case Study 2: The Ethiopian Wolf

The Ethiopian wolf *Canis simensis* (Fig. 3) is an Afroalpine specialist, endemic to the Ethiopian highlands above 3000 m (Gottelli and Sillero-Zubiri, 1992). Its diurnal habits and distinctive coat make it conspicuous. The species evolved in the geographically isolated Ethiopian massif, where it became highly adapted to prey on the abundant Afroalpine rodent fauna. Unlike other canids which have a broad diet breadth, its diet is mainly comprised of diurnal rodents, with the giant mole rat (Fig. 4) being the predominant prey (Gottelli and Sillero-Zubiri, 1992). The morphology of their skull reveals adaptations for catching rodents, such as a very elongated skull, long jaws and widely spaced teeth (mainly the premolars) (Clutton-Brock et al., 1976; Yalden and Lagen, 1992; Sillero-Zubiri and Gottelli, 1994). Unlike other pack-living wolf species, the Ethiopian wolf is a solitary forager. It is mainly because of these feeding specializations that they are now on the verge of extinction, as discussed below.

Threats to African Alpine Environment

Like most ecosystems on the planet, Afroalpine habitats are being negatively impacted by human activity and encroachment. Life here is threatened by a combination of serious threats related to loss of habitat and/or habitat change as a consequence of the combined effects of clearing land for farming and land degradation due to livestock grazing. Civil war in several African

countries has also disturbed many Afroalpine habitats. Displaced people may seek refuge at high elevation, destroying natural habitats and supplementing their diets with bushmeat (Tefera, 2011). Ultimately, global climate change will exacerbate some of these already fragile refugia for many species (Tefera, 2011). The loss of biodiversity is likely to occur unabated for the foreseeable future.

The impacts of such environmental changes are not well documented for Afroalpine mammals. Some expected impacts of expanding human population and their livestock are linked to a variety of threats to wildlife. For example, the Northern groove-toothed rat is adapted to humid swamp grasslands in Ethiopia but is now absent in areas which are heavily grazed (Ashenafi et al., 2012). Similarly, an increase in human disturbance has negatively affected the genus *Otomys* (Monadjem, 1997, 1999). In Ethiopia, the mountain nyala and other antelopes compete directly with livestock for food and are usually absent from areas where livestock numbers are high (Brown, 1969).

Clearing of natural Afroalpine vegetation for farming is occurring at an alarming rate (Lemenih and Teketay, 2006; Bogaert et al., 2008; Skarbek, 2008). The Bale monkey *Chlorocebus djamdjamensis*, an arboreal primate endemic to the southern Ethiopian highlands, is susceptible to extinction because of the rapid clearance of bamboo forest; it feeds on the leaves and stems of a single bamboo species (Mekonnen et al., 2010). Consequently, crop raiding and hybridization with other *Chlorocebus* taxa might drive the Bale monkeys to extinction.

More is known about the charismatic Ethiopian wolf whose decline as a consequence of habitat loss and risk of persecution by people has been documented (Yalden and Largen, 1992). These apex predators face a barrage of other threats, including infection by rabies transmitted by domestic dogs (Sillero-Zubiri et al., 1996; Marino et al., 2006). There has also been a marked decline in its rodent prey base, particularly the giant mole rat, whose numbers have been diminishing because of overgrazing of its grassland habitats by domesticated animals (Ashenafi et al., 2012; Busby et al., 2006).

The impact of natural fires in Afroalpine regions has direct and indirect influences on small mammal populations. Some species, such as *Otomys* spp. and *Rhabdomys* spp. in the Afroalpine region of Mt. Elgon, Uganda, benefit from fire-induced habitat changes that turn ericaceous forests into grasslands; frequent fires lead to patchy grassland distribution which confers benefits to *Rhabdomys* spp. (Clausnitzer, 2001).

Fire can kill individuals or make an area uninhabitable due to loss of vegetation and cover (Fuller and Perrin, 2001; Abera and Kinahan, 2011). Humans also use fires to alter Afroalpine habitats. For example, to increase forage for their livestock, herders in Ethiopia and Uganda regularly burn large expanses of *Erica* plants prior to the spring rains to open the landscape and promote germination of vascular plants. Although this practice is presumed to be decades old, historical accounts (e.g. Hedberg, 1971) suggest that it was never as widespread or destructive as it has been in recent years (Wesche et al., 2000). The impact of such burning on mammals in this region is not known.

Little is known about how mammals themselves shape their Afroalpine habitats. In one exception, Mokotjomela et al. (2009) erected enclosure plots to investigate the single or combined effects foraging/burrowing of ice rat and foraging/trampling by domesticated livestock on the vegetation and soil characteristics in their alpine habitats, and whether these activities potentially influence soil erosion (Fig. 5). In this year-long study, ice rats appeared to be a greater contributor to vegetation change and soil movement than livestock. The impact of the species is apparently linked to increased population growth. Ice rat survival depends on the severity of the winters, with persistent low temperatures being detrimental for this physiologically poorly-adapted rodent. The winters have been comparatively mild in recent years, potentially related to global climate change, leading to better over-winter survival of ice rats (Mokotjomela et al., 2009; Pillay and Rymer, 2017). Thus, it is possible that ice rats could alter the ecological balance in the Drakensberg Mountains (Mokotjomela et al., 2009). Nonetheless, a 10-year study by Grab (2012) showed that the impact of ice rats might not be as dramatic because of the episodic spatial shift of ice colonies to new areas of greater foraging potential, allowing for the recovery of previously degraded areas.

Fig. 5 The impact of ice rat behavior on their habitat. Note the collapsed flooded burrow system. Courtesy of Stefan Grab.

Concluding Remarks

The Afroalpine zone represents isolated pockets on mountain tops, stretching over a vast geographic distance. Unsurprisingly, each Afroalpine zone has a unique set of mammalian species, comprised mainly of rodents. Some charismatic species have evolved on these isolated mountains, notably the Ethiopian wolf and giant mole rat. Afroalpine zones contain a large number of endemic mammal species, making them refugia for biodiversity. Thus, the future management of Afroalpine ecosystems are critical for the conservation of endemic species. We relied on the literature, our own experience and input from colleagues to describe Afroalpine mammal diversity. However, cataloguing the Afroalpine mammal diversity and its conservation requires continued focused fieldwork in many countries. Long-term sampling is needed to detect changes in population sizes and the vulnerability of species to extinction. Moreover, focused research on the adaptations of selected Afroalpine mammals, such the ice rat, will provide useful foundational knowledge and also highlight their plight under global climate change. Such research is critical but may prove challenging because Afroalpine zones are often remote and there is a dearth of field biologists working in these zones.

Abstract

This article discusses the mammalian wildlife of the alpine regions of Asia. These include about 76 species, ranging from small rodents to large ungulates and their predators. The wild mammals of these regions are a unique, irreplaceable biological resource that deserve our protection. Eight of these species are endangered and two are critically endangered. All highland mammals of Asia face threats from habitat degradation and loss, the impacts of domesticated ungulates, intrusion into formerly pristine highlands by farms, roads, and fences, impacts from hunting, and trapping and poisoning by poachers and herders. The common denominator here is the human population of the Asian highlands, which used to be extremely small and based solely on subsistence farming and herding. It has grown incredibly and now stands at about 40 million. People and wildlife are increasingly coming into contact as the wild spaces decrease, and the human populations grow. This causes conflict as wild animals destroy crops and kill livestock.

Introduction

The countries considered in this article include, from west to east, Uzbekistan, Afghanistan, Pakistan, Tajikistan, Kazakhstan, Kyrgyzstan, India, Nepal, Bhutan, China, southeastern Russia, and northern Myanmar (Fig. 1). These countries are home to numerous mountain ranges, including, from west to east, the Hindu Kush, Pamirs, Karakoram, Tien Shan, Kunlun Shan, the Altai Mountains, and the Hengduan Shan. The Greater Himalayan Range sweeps across northern India, Nepal, Bhutan, and southwest China. To the northeast of this range lies the Tibetan Plateau, the highest major plateau in the world, with average elevations of 5000 m. As shown in Fig. 1, these mountain ranges are extensively glaciated, especially in the eastern regions. The melting of winter snows and glacial ice feeds some of the most important river systems of the continent, including the Indus, the Brahmaputra, the Ganges, the Yangtze, the Yellow River, the Mekong, and the Irrawaddy.

Regional Environments

The alpine regions of Asia are generally inhospitable to vertebrate life. The winters are very long and incredibly cold, with potentially lethal air temperatures persisting for several months of the year. Summers are short, and the length of the growing season decreases with elevation. The growing season in high elevations above treeline average 50–60 days. The highest peaks have only sparse, intermittent plant cover. The short growing season and cold climate lead to a paucity of food resources in the high alpine. Thus, the diversity of plant feeding mammals is low here. Because of the thin air, summer daytime temperatures in the alpine vary greatly, depending on location.

The decrease in air temperature due to increasing elevation shapes many aspects of alpine climate. The temperature lapse rate (TLR) is mainly controlled by the topography and climatology of the region. Mean lapse rate in the Himalayas varies from 0.43°C per 100 m in January to 0.61°C per 100 m in April, with monsoon moisture associated with the lower lapse rates for the region

Fig. 1 Map of Asia, showing the countries and mountain ranges discussed in the text.

(Kattel et al., 2013). High mountains in the mid-latitudes of Asia have afternoon temperatures in the summer months that average only about 5–9°C, and many night time temperatures fall below freezing. A weather station at the base camp on Annapurna in the high Himalayas (4130 m above sea level) records minimum temperatures above freezing from May to early September. A weather station at 4794 m elevation on Mount Xixibangma in Tibet shows differences between monthly high and low temperatures of 12–14°C. Here, summer temperatures rise to 17°C, and winter temperatures fall as low as –18°C in February. The wettest, least windy sites are dominated by snow beds, which persist into late summer, leaving behind soils saturated with melt water for a few brief weeks before snowfall resumes.

The Karakoram Range is essentially a desert. The average annual precipitation does not exceed 100 mm. At elevations above 4900 m, precipitation always falls as snow. At heights between 3900 and 5700 m, summer temperatures are lower than 10°C. At elevations of about 5700 m, the average temperature during the warmest month is below freezing.

The climate of the Tien Shan Mountains features extensive areas of permafrost above 2750 m. The maintenance of permanently frozen ground requires average annual temperatures below 0°C for two or more years. The temperature in July at 3200 elevation in the inner Tien Shan averages 5°C, and frost is possible throughout the summer. Winter temperatures of –23°C are common in the alpine regions of the inner Tien Shan; in some localities, especially the Ak-Say valley, winter temperatures fall as low as –50°C.

Human Population of Asian Mountain Regions

The mountainous countries of mid-latitude Asia are home to over 3.3 billion people. This represents 43% of the global population. Of course, only a small fraction of these people live in the mountains of their respective countries, but it is clear that human populations in the mountainous regions of Asia have been growing steadily since the end of the Second World War. At that time, the total population of these Asian countries was 1.1 billion, just one-third of what it is today. Table 1 shows the current and 1945 populations of the eleven countries discussed in this article. Table 2 shows the current populations living in the mountain ranges of those countries. Increasing human populations in these Asiatic mountains pose multiple threats to high elevation mammal populations. These threats include over-hunting of large mammals, competition for grazing from domesticated animals, habitat dissection from roads, fences, farms, villages, and other man-made obstructions, and habitat loss due to changing land-use

Table 1 Human population of the mountainous countries of mid-latitude Asia

<i>Country</i>	<i>Area (km²)</i>	<i>2019 Population (millions)</i>	<i>1945 Population (millions)</i>
Uzbekistan	447,400	32.81	6.45
Afghanistan	652,237	37.21	12.6 (1954)
Pakistan	881,913	197	32.74
Tajikistan	143,100	9.24	1.51
Kazakhstan	2,725,000	18.54	6.44
India	3,287,000	1370	360.1 (1951)
Nepal	147,180	29.94	6.84
Bhutan	38,394	0.83	0.65 (1950)
China	9,597,000	1420	537.53
Myanmar	676,575	54.34	15.65
Russia	17,100,000	143.89	106.0

Table 2 Human population of the mountain ranges of mid-latitude Asia

<i>Mountain range</i>	<i>Area (km²)</i>	<i>2019 population (millions)</i>
Greater Himalayan range	660,000	50
Hindu Kush	232,000	210
Pamir	118,000	0.016
Karakoram mountains	22,600	0.815
Tien Shan mountains	2,592,000	4.1
Kunlun mountains	570,000	0.254
Hengduan mountains	360,000	0.250
Southern Altai mountains	328,000	0.612

practices. Because of population pressures, people are now living at higher elevations in these mountain ranges, and they are extending pastoral rangelands into formerly pristine alpine regions.

Mammals of the Asian Alpine

According to the most recent estimate (Burgin et al., 2018), there are 6400 species of mammals in the world today. Most of these live in the tropical regions, with Brazil ranking first among the nations for greatest number of mammal species (600). The number of mammal species (and most other groups of organisms) decreases towards the poles and with elevation in mountainous regions. This article deals with the mammalian fauna of the Asian alpine region. As shown in Table 3, this region is home to about 76 species of mammals. There is a high degree of endemism in the alpine mammal species of Asia. Endemism refers to a species that is restricted to a particular geographic region as a result of factors such as isolation or in response to abiotic conditions. In the case of alpine mammals, both conditions apply, that is, species living in the alpine are geographically isolated from species in other regions, and they are highly adapted to the rather severe abiotic conditions of cold climate, short growing season, high winds, rocky substrates, and other abiotic factors.

IUCN Classifications

The International Union for Conservation of Nature (IUCN) has established a set of standards to classify the conservation status of wildlife (Table 4). Classifications of more than 98,500 species of plants and animals have thus far been made. The information is made available through the IUCN Redlist web site. This site provides information about range, population size, habitat and ecology, use and/or trade, threats, and conservation actions that help inform conservation decisions by governments and international agencies. Fortunately, most mammal species of the Asian alpine regions are not immediately threatened with extinction, but a few species are critically endangered.

Small Mammals (Fig. 2)

Small mammals, such as voles, shrews, pikas and lemmings, have a very large surface-to-volume ratio. This causes them to lose a great deal of heat to the environment during the winter. Not surprisingly, then, the small mammals of the Asian alpine avoid exposure to winter air temperatures to the best of their ability. Most of them gain protection from winter air temperatures by tunneling beneath the snow. Snow provides excellent insulation from cold air temperatures.

Table 3 IUCN conservation status and ranges of alpine mammals in Asian countries/regions[illegible]

[illegible]

Table 4 Definitions of the IUCN species conservation classification system

<i>IUCN classifications</i>	<i>Definition</i>
Extinct (EX)	Beyond reasonable doubt that the species is no longer extant
Extinct in the wild (EW)	Survives only in captivity, cultivation and/or outside native range, as presumed after exhaustive surveys
Critically endangered (CR)	In a particularly and extremely critical state
Endangered (EN)	Very high risk of extinction in the wild
Vulnerable (VU)	Meets one of the five red list criteria and thus considered to be at high risk of unnatural (human-caused) extinction without further human intervention
Near threatened (NT)	Close to being at high risk of extinction in the near future
Least concern (LC)	Unlikely to become extinct in the near future
Data deficient (DD)	Insufficient information on the conservation status of a species

Information from IUCN (2019). The IUCN Red List of Threatened Species. Version 2019-1. <http://www.iucnredlist.org>.

A study of temperatures beneath snowbanks in Svalbard showed that temperatures beneath just 30 cm of snow remained extremely stable and did not fall below -2°C , even though air temperatures above the snow dropped as low as -24°C (Convey et al., 2015). These stable, near-freezing environments beneath the snow allow some small alpine mammals to remain active during the winter. Tunnels made by small mammals beneath the snow are not only substantially warmer than the air above, they also hold considerable moisture. This relatively warm, moist air helps small mammals avoid both the freezing and desiccation they would face on the surface. Johnsen et al. (2017) examined vole survival in mountain habitats and found that high elevation environments showed greater stability. They had lower temperatures, deeper snow, and longer lasting snow cover than those at low elevations. Thus, perhaps counterintuitively, mild winter conditions contributed to more vole fatalities. Cold conditions, with deep, stable snowpack, enhanced vole survival in high alpine environments, because of improved subnivean conditions.

Voles

The voles of the Asian alpine regions are incredibly diverse, with thirteen species representing six different genera (Table 3). Most of these species are not threatened by population declines or habitat loss, except for two: Royle's mountain vole (*Alticola roylei*) and the burrowing vole (*Hyperacrius fertilis*). These two species are in the "near threatened" category of the IUCN. Royle's mountain vole is decreasing in numbers, chiefly because of habitat loss and fragmentation due to grazing of domesticated animals in the alpine zone. The burrowing vole is threatened by habitat fragmentation, causing small populations to become isolated from each other. Many of the alpine voles of Asia store foods underground in order to survive the winter. For instance, the root vole (*Microtus oeconomus*) begins accumulating food in late September. They store their winter foods in previously excavated underground storerooms, and spend the winter underground, thus avoiding exposure to the extreme cold temperatures at the surface. Snow cover is apparently essential to vole survival in alpine winters. Johnsen et al. (2017) noted the differences in alpine vole survival related to the depth and stability of the snowpack. Vole populations living at high elevations having greater winter survival rates, because the lower temperatures, deeper snow, and longer lasting snow cover in the high country ensure that the voles have better, longer-lasting snow cover than those living at lower elevations.

Ground squirrels and marmots

Unlike some other alpine regions of the world, the Asian alpine is home to only one species of ground squirrel, the Alashan ground squirrel (*Spermophilus alashanicus*). This ground squirrel lives in China and Mongolia. It occupies a wide range of habitats, from the steppe zone and the foothills regions, up to alpine meadows. In China it can also be found in desert habitat. This ground squirrel falls in the "Least concern" category of the IUCN, as its population appears to be stable.

The marmots of the Asian alpine are quite diverse, with four extant species: the Altai marmot (*Marmota baibacina*), the Long-tailed marmot (*M. caudata*), the Himalayan marmot (*M. himalayana*), and the Mongolian marmot (*M. sibirica*). Marmots form part of snow leopard prey. All but the Mongolian marmot are categorized as "Least concern" by the IUCN. The Mongolian marmot is endangered. This is because the population is severely fragmented. *Marmota sibirica* is a social, colonial-living rodent that ranges widely throughout northern Asia. This marmot was once common in Mongolia, but hunting has fragmented its distribution, leading to an estimated 70% decline in population size during the 1990s. Since then, its numbers are believed to have declined even further. In Russia the species is rare and declining. Mongolian hunters kill these marmots for their meat and skins, which fetch high prices now that the species has become rare. The government of Mongolia set limits on the number of Mongolian marmots that could be taken by hunters. However, recent surveys estimate that actual numbers of skins sold exceed the hunting quotas by more than three times. Over 117,000 illegally traded marmot skins were confiscated in 2004. There has been an increase in hunting since the price of pelts increased and factors such as the improvement of roads is providing better access for hunters to find marmot colonies.

The Siberian marmot is often considered a keystone species because its burrows are an important resource for a variety of taxa, including carnivores (Murdoch et al., 2009). Keystone species are species on which other species in an ecosystem largely depend; if the keystone species were removed, the ecosystem would change drastically. Among the species that make use of these marmot burrows in steppe regions is the corsac fox (*Vulpes corsac*). Corsacs regularly make use of marmot burrows. The burrows are thus important resource for foxes, supporting the notion of the Mongolian marmot as a keystone species.

Cricetulus alticola
(Tibetan dwarf hamster)

Microtus gregalis
(Narrow-headed vole)

Alticola argentatus
(Silver Mountain vole)

Ochotona curzoniae
(Plateau pika)

Ochotona thibetana
(Moupin pika)

Ochotona hyperborea
(Northern pika)

Alticola roylei
(Royle's mountain vole)

Alticola stoliczkanus
(Stoliczka's mountain vole)

Marmota sibirica
(Mongolian marmot)

Marmota himalayana
(Himalayan marmot)

Lepus oiostolus
(Woolly hare)

Hemiechinus auritus
(Long-eared hedgehog)

The Himalayan marmot (*Marmota himalayana*) is one of the largest marmots in the world, stoutly built with short legs and a small stubby tail. They weigh up to 9 kg and are up to 67 cm long. The Himalayan marmot is regarded as an ecosystem engineer because of the effect of its burrowing on soil fertility and plant diversity in the mountain ecosystems. Unfortunately, Himalayan marmots are considered pests in parts of the Asian highlands, and in some areas they are killed by farmers. Like the Mongolian

marmot, the Himalayan marmot is also killed for fur and meat. In affected areas, harvesting for illegal trade and lethal control are considered the major causes of decline of marmot populations.

A study of Himalayan marmot habitats by Chaudhary et al. (2017) found that this species most often lives between the upper treeline and the snowline of the highlands of Asia. The maximum number of marmots were observed at elevations above 4000 m. Steep slopes with loose soil are the preferred habitat of these marmots, due to ease in excavation of their burrows. This marmot lives in colonies and excavates deep burrows that colony members share during hibernation. Burrows are up to 10 m deep, depending on soil type. Where soil conditions are ideal on alluvial terraces, marmot colonies comprise up to 30 families, with up to 10 families living in an area of 1 km. This species feeds on plants growing in alpine meadows, in particular the soft parts of grasses.

Su and Liu (2000) studied the overwintering strategies of small herbivorous mammals inhabiting alpine areas of China (Fig. 3). Observations were concentrated on the five most common species: Himalayan marmot, plateau pika, Gansu pika, root vole, and plateau zokor. These animals use three main strategies to survive the winter. The Himalayan marmot was the only hibernator in this group. It hibernates from late September to the mid-April. It therefore did not need to store food for winter. The plateau zokor was the only subterranean rodent among the nonhibernators. It typically starts to store food for winter by the middle of September—the time when juveniles are able to leave their mothers to live separately. Food gathering ends in late October or early November when soils freeze, making further burrowing impossible. Root voles begin to store food in late September. They store winter foods in underground storerooms that have been dug previously, thus avoiding exposure to extreme cold temperatures. Gansu pikas collect and dry herbs (hay making) in late September. They harvest plants and cache them above ground at locations within 1 m of their burrow openings. Plateau pikas that live in meadows store large amounts of forage in hay piles, for later consumption. Interestingly, however, it appears that food limitation in the cold season is not an important factor influencing the mortality rate of pika (Qu et al., 2013).

Why did small herbivorous mammals in the alpine area adopt different wintering strategies? First, the high risk of predation may prevent small mammals from hibernating. Second, fat deposits are needed to survive during both hibernation and posthibernation activity that occurs before new food becomes available in the environment, so small-bodied species cannot afford to practice hibernation because they cannot store sufficient fat deposits to carry them through winter. These factors explain why the Himalayan marmot was the only hibernator in this study. Third, the life history and adaptations of these small mammals play a role in how they overwinter. For instance, the plateau zokor is a nonhibernating subterranean rodent; it lives on the underground parts of plants. If it does not excavate enough tunnels in the soil before winter begins, it will die from starvation because foraging by burrowing in frozen soils is impossible. Fourth, an animal's tolerance to cold, correlated to body size, determines its cold exposure limitations and thus its method of overwintering. This can be used to explain the differences of wintering strategies adopted by plateau pika, Gansu pika, Chinese zokor, and root vole. The differences in feeding strategies of these four small herbivores (Fig. 3) allow them to occupy overlapping territories without directly competing for food resources. The wintering strategies of these animals has been shaped by the long process of natural selection.

Hares and pikas

Only two species of hares are found in the Asian alpine, the woolly hare and the mountain hare. Both species are in the “Least concern” category. The woolly hare is found in China, India, and Nepal. The mountain hare ranges widely throughout northern Eurasia. The conservation status of the woolly hare in Tibet has been examined by Lu (2011). Woolly hares range up to 5500 m elevation in this region, representing the highest distribution of *Lepus* hares in the world. Human activities, mainly livestock grazing, are exerting heavy pressures upon the alpine grassland and meadow ecosystems in Tibet. As a result, natural vegetation has become heavily degraded. However, alpine shrub vegetation persists in protected valleys, allowing woolly hares to survive there. In contrast

Fig. 3 Overwintering strategies of small herbivorous mammals inhabiting alpine areas of China. Data from Su, J., Liu, J. (2000). Overwinter of small herbivorous mammals inhabiting alpine area. *Acta Theriologica Sinica* 20, 186–192.

to the limited distribution of the woolly hare, the mountain hare ranges from the British Isles to northeastern Siberia, living in both forests and arctic and alpine regions. This species is notable for its fecundity. Adult females are able to give birth to up to 24 leverets (offspring) per year.

The highlands of Asia are the center of origin for pikas. Here they achieve their greatest species diversity: 18 species. Ten additional species live at lower elevations in Asia. By comparison, in North America there are only two species of pika. Of the 18 alpine pika species in Asia, 14 are considered “Least threatened,” one is “Data deficient,” and three are endangered. These include the silver pika (*Ochotona argentata*), the Ili pika (*Ochotona iliensis*), and Kozlov’s pika (*Ochotona koslowi*). According to the IUCN (2019), there are currently only three populations of the silver pika, all from the Ningxia Hui Autonomous Region of north-central China. Populations are declining because of habitat loss. The Ili Pika is endemic to the Xinjiang Autonomous Region of northwest China. It is known only from two spurs of the Tian Shan Mountains and the Ili pika has a highly fragmented distribution within this restricted geographic range. Population declines have been observed for several locations inhabited by this species. Upon its initial discovery in 2005, the Ili Pika was determined to occupy 14 locations: 12 in the north spur of the Tian Shan, two in the south spur. It currently occupies only four of these sites, none of which are in the south spur. Even in occupied localities, the population density is very low and apparently declining. According to Li and Smith (2005) the Ili pika also has a low rate of reproduction. Additionally, populations on its preferred habitat of cliff faces are highly fragmented. Increased temperatures, possibly due to global warming, and increased grazing pressure from domesticated yaks may have interacted with the normal population dynamics of the Ili pika to contribute to its recent dramatic decline.

According to the IUCN (2019), Koslov’s pika was found to be locally abundant as recently as 1999. However, recent surveys have documented severe declines in the number of extant populations as well as overall population density in the remaining studied populations. It is currently known from only ten locations, all in the Xinjiang Autonomous Region of northwest China. Like other pikas, this species reproduces only once a year, producing 4–8 young per litter.
